PROGNOSIS OF STERILITY*

EDWARD REYNOLDS, M.D.
BOSTON

The treatment and more especially the operative treatment of sterility differs essentially from the treatment of ill health in that in the latter treatment is a matter of necessity, while in sterility it is frequently a matter of the patients' choice, of their readiness to submit to operation, or to perhaps tedious minor treatment, merely for the sake of future gain and happiness. For this reason an exact statement of the prognosis, of the degree to which success can be expected the individual case, is of perhaps greater importance than in any other branch of surgery.

The importance of this point and the fact that the subject of sterility is so complex that a full review of even one phase of it can be with difficulty compressed within so short a space, is the reason that this paper must neglect treatment and even the details of diagnosis in order to cover prognosis even roughly.[1]

At first sight the most obvious method of dealing with this subject would be by the statistical study of cases treated, but apart from the complexity of the subject and the enormous number of cases which would be necessary for an adequate study of the several classes of sterility, a statistical presentation is rendered useless by the practical fact that so soon as one's study of sterility begins to bring him any considerable number of reference cases he sees an increasingly large proportion of cases which are on their face hopeless, the patients having traveled from place to place hoping against hope. The exclusion of these cases from his statistics would make them unconvincing and unreliable; their inclusion would make the results practically useless;[2] and further the only point which is of practical value is the attainment of an accurate prognosis in individual cases under the several classes of sterility, rather than a general statistical statement which would be of little value, and which, from the complexity of the subject, is all that could be obtained statistically from any number of actually observed cases which could today be collected.

In order to obtain a fair conception of the prognosis in any given case we must consider sterilities under a classification by causation, and must discuss, first, the prognosis in each of these classes by itself, and, later, the prognosis in the many cases in which the sterility is due to more than one of these causes.

We may begin such a classification by dividing sterilities into those which are dependent on absence or inferior quality of the ovum, those which are the result of secretions of the genital tract which are destructive to either the ovum or spermatozoa, and finally those which are due to absence or inferior quality of the spermatozoa. In each of these classes we have cases which are organic in nature, that is, due to local or anatomic abnormalities; and in each we see cases which are functional and due to abnormal constitutional conditions of the individual. We have, then, at least six classes to start from, and most of these must later be subdivided.

We are profoundly ignorant of the chemistry of the reproductive organs. We can then draw con[illegible]sions about the functional cases only from anal[illegible] with facts which have been more or less well es[illegible]lished in the breeding of animals and by the very small amount of direct experimental work which has been done along lines bearing on sterility. After about three years of some personal study on this point in domestic fowls, and of inquiry among breeding farms devoted to animals it seems to be probably an established fact that, in animals, fertility is decreased both by undue obesity in either sex and by excessive overwork. There is also some reason to believe that conditions of life which produce marked nervous ex[illegible]bility decrease fertility in animals, and this must [illegible] remembered in connection with many of the condit[illegible] of civilized existence in the human race. We h[illegible], however, no knowledge of the mechanism by w[illegible] such alterations of condition produce relative or c[illegible]plete sterility in animals. We do not even k[illegible] whether it is effected by decreased quality of the [illegible] or spermatozoa of the individuals, or by alteration of the chemical composition of the fluids in which these gonads are immersed.

Sc., August, 1907; Anteflexion of the Cervix and Spasm of the Uterine Ligaments in Relation to Retroversion, Dysmenorrhea and Sterility, Surg., Gynec. and Obst., July, 1911, p. 17; The Ultimate Results of the Conservative Surgery of the Ovaries, Surg., Gynec. and Obst., March, 1912, p. 255. Reynolds, Edward: The Theory and Practice of the Treatment of Sterility in Women, THE JOURNAL A. M. A., Jan. 11, 1913, p. 93; Further Points on the Sterility of Women, ibid., Oct. 11, 1913, p. 1363.

[2] As an illustration: After selecting, in preparation for this paper, a certain date from which a statistical investigation of personal cases should begin, and assembling all the cases seen since that date, the first seven cases showed the following conditions: Patient 1, both tubes and one ovary previously removed for tuberculosis. Patient 2, large pelvic masses after repeated operations for peritonitis"; condition of husband unknown. Patient 3, both tubes enlarged; two previous abdominal operations; will contemplate nothing but minor treatment. Patient 4, ten years of gonorrheal salpingitis in first marriage; two previous operations; demanded operation in spite of bad prognosis; both tubes found ruined. Patient 5, aged 44; previous operation for genital tuberculosis; polypus of cervix; husband not accessible. Patient 6, husband partly impotent and refuses examination. Patient 7, anteflexion of the cervix, pinhole os, plastic operation; pregnant three months afterward. Here [illegible] six hopeless cases were found before one was favorable. In nea[illegible] hundred cases which were abstracted before the attempt was give[illegible] the proportion of hopeless cases proved indeed to be smaller than [illegible] but was still so high as to vitiate statistical conclusions. The [illegible]centage of hopeless cases was, moreover, found to increase in a ge[illegible] relation to the distance from which the patient had been referred, hinting in another way that a prognosis drawn statistically from such a list as this would not show fairly the prognosis of sterility in cases as the practitioner sees them, or as they exist in the community at large.

We know even less about this question in the human race. We however know a little more about this point in the human male than in the female on account of the ease with which the spermatozoa can be directly inspected and because of the impossibility of finding the ovum. We have direct evidence that in the human male an excess of mental work sometimes results in the disappearance of spermatozoa from his semen, and some direct evidence that an excess of fat may produce the same result. We have also probable clinical evidence that the excessive use of alcohol and perhaps the extremely excessive use of tobacco decrease the vitality of his spermatozoa even though they be still present and of normal appearance. We have absolutely no evidence concerning the effect of these general conditions on the ovum, and can only surmise that they may well have the same effect on the gonads of the female that they have on those of the male. This weakness of our knowledge of the functional conditions is necessarily a constant embarrassment in our interpretation of the importance of the organic or anatomic abnormalities which we detect in a given case.

In spite of this extremely unsatisfactory state of our scientific knowledge it is, however, possible to obtain very satisfactory practical results in the prognosis of individual cases by the assumption of the following working hypotheses:

1. When the spermatozoa are abundant in number, normal in form and appearance, furnished with long cilia and capable of rapid movement through the semen the male is satisfactorily fertile.

2. When normal spermatozoa are killed or lose vitality overrapidly in the secretions of the individual woman, the chemicophysiologic character of her secretions furnishes an effective cause of sterility.

3. The alterations in a secretion which make it fatal to the spermatozoon may be localized in the vagina, the cervix, in the body of the uterus, or in one or h tubes; and any one of these alterations may exist with normal secretions above it; but an alteration in the secreting surface in any of these localities usually vitiates all the secretions below it, probably by their necessary admixture.

4. When the spermatozoa are observed to penetrate without apparent loss of vitality to the fundus of the uterus and to survive there for a normal length of time, deficient quality of the ova may be considered the probable cause of the sterility.

Throughout the management of every case of ster- it must be remembered that the failure is the ure not of one individual, but of a couple, and that condition of both partners must be studied.

If these hypotheses are borne steadily in mind oughout the study of a case, and if the variations in conditions which affect them are studied and udied by all the methods which are now at our dis- al, it becomes surprising to see how practically good rognosis can usually be made in spite of our lack exact physiology and chemistry, but, on the other nd, it is certainly true that so long as we labor under these defects of theoretic knowledge, a painstaking exactness in the observation of details will be the first prerequisite to success.

In the practical management of such a case the first step is the taking of a careful history, which should not be confined to the history of the sterility alone, but should follow every detail of the past health of both patients, since many sterilities are dependent on slight pathologic alterations in the genitals on which great light is often thrown by past symptomatology. The history and physical examination should also include a careful study of the general condition and especially of the nutrition and habits of life of both partners, such factors as obesity, emaciation, nervous debility, drug habits, sleeplessness from overwork, etc., in either partner, being all important. Furthermore, distasteful as the subject is, he who is to handle sterility successfully must acquire the art of obtaining full and accurately truthful histories of the sexual habits of the couple, with especial reference to any abnormalities, even if apparently minor, in either the sexual appetite, or the methods employed in the performance of coitus. There is certainly a steady percentage of cases in which these matters are all important. The next step in the management of the case from a practical standpoint is usually a careful examination of the genital tract of the woman step by step, remembering that minor abnormalities which are unimportant to health, that is, which create no symptoms of importance, are often abundantly competent to produce infertility. I constantly see cases which have been pronounced normal even by excellent gynecologists and in which the organs are normal from the standpoint of health, but in which there is nevertheless some minor abnormality which is perfectly evidently the cause of the sterility, as is often shown by the fact that when this is remedied impregnation occurs without further treatment. This examination must include study of the condition of the vagina, cervix, uterus (including the character of their secretions), tubes and ovaries, and it must be remembered that the detection of the minor abnormalities of the tubes and ovaries almost always requires an examination under anesthesia.

When all this has been gone through with sufficient care the surgeon should be in a position to estimate with considerable closeness both the anatomic and functional condition of the woman and should have an equally good estimate of the general functional condition of her husband.

In the majority of cases the next step should be a form of examination which has been lately given to the profession by the ingenuity of Dr. Max Huhner of New York, the microscopic examination of the spermatozoa in situ in the genitals of the woman, of which much will be said in the remainder of this paper, but dramatic and interesting as this test is, it must always be remembered that it can furnish at most only one element in our study of a case.

This test not only furnishes an examination of the man which is in most cases thoroughly satisfactory, but also enables us to check the conclusions previously arrived at as to the relative importance of anatom and functional conditions by direct observation much of the process of fertilization while actually progress. Experience has, however, convinced me th this process of observation must, like so many oth exact methods, be considered by the wise clinician furnishing only one link in the chain of evidence. is so interesting and dramatic that it is extremely ea to overestimate its value, and to be led by it to fa conclusions, if we fail to consider its results in connection with those obtained by other methods of observation. If the conclusions arrived at by both methods are substantially in agreement, even to details, we may safely trust them. If the two methods yield different results we should distrust our conclusions, for we are then certainly not in a position to act until further study has reconciled their discrepancies. To pin our faith to either method will usually lead to false conclusions.

For the performance of the Huhner test we must ask to see the woman as soon as possible after coitus has taken place. She may come to the office for this examination, since it is only very exceptionally, if ever, that the vagina does not contain sufficient spermatozoa for this test even after she has walked about for some time. With a normal vaginal secretion the spermatozoa should show active motility in the vagina for about an hour and sometimes much longer, but if circumstances permit it is desirable that the patient should be seen within half an hour of coitus. A specimen of the vaginal mucus is taken by a sterile platinum wire from the culdesac, exposed by a speculum, and this examination may be repeated if desired, whenever convenience permits, until the spermatozoa are found to have lost their activity. A specimen of the cervical mucus is next obtained in the same way, after the surface of the cervix has first been carefully wiped clean of semen by the repeated use of cotton swabs (no antiseptic should be used). With a normal cervical secretion and a normal os a few spermatozoa will usually be found in the lower part of the cervical cavity almost immediately after coitus, but will appear there in larger numbers at the end of half an hour to an hour. They are never so numerous here as in the vagina, but under normal circumstances, at the end of an hour, there should be several actively moving spermatozoa in each slide from the cervical mucus. The greatest care should be used to avoid the infliction of any trauma in the examination of the cervical cavity, since overthoroughness here may readily vitiate the use of the remaining portion of the test at that sitting.

When the cervical cavity has not been unduly disturbed, when the spermatozoa are of full vitality, and when the secretions of the woman are normal throughout, an examination of the secretions of the cavity of the uterine body should disclose the presence of a few actively motile spermatozoa in the uterine mucus at the end of from two to three or four hours. This examination must however be made with a specially devised syringe, since the platinum loop can neither be introduced with certainty to the fundus nor made to retain the uterine mucus during its withdrawal from the cervix. Even with the use of a syringe it is difficult to be absolutely sure that spermatozoa which are observed in the fluid withdrawn from the uterus are not due to an admixture from the cervix, but if the piston is not withdrawn until the tip of the syringe is well up in the uterine cavity, if the outside of the ringe is carefully wiped after withdrawal, if it is perly designed, and especially if the spermatozoa found several times in succession, their probable ation in the uterine mucus can be predicated. In ne cases it will be found that actively motile spermaoa have disappeared from the cervix after the lapse a number of hours but are still found in the uterine cus. In these cases the test is practically complete. This study of the process of fertilization while it is actually in progress seems most rational and is in many cases extremely satisfactory, though care must always be used in its interpretation, as will be developed further later. The results obtained from it have led me to be a believer in the probable existence of that much mooted phenomenon, relative fertility; that is, I can now believe that a woman with slightly altered secretions may be sterile to a man with only moderately vitalized spermatozoa, and yet fertile to a man whose abundant and highly vital spermatozoa can resist her slightly hostile secretions; while, on the other hand, the moderately vital spermatozoa of the first man might succeed in effecting conjugation with the ovum through the absolutely normal secretions of another woman. On this latter point I have had fairly direct evidence, that is, I have seen instances in which with improvement in the secretions of the woman comparatively poor spermatozoa became able to make effective progress.

The Huhner test, valuable as it is, must however not be relied on too far lest it lead us into a too mechanical view of the problem of sterility. It requires for its successful use considerable tactile skill and no inconsiderable familiarity with the microscopic appearances to be noted, and there is undoubtedly much yet to be learned, from the microscopic point of view, by wider experience in the use of this test. It is not adapted for experimental, empiric use by the general practitioner, nor is it safe unless carried out with the most complete asepsis.

The several observations which may be made by this method will now be summarized, and their bearing on the results of other methods of examination will then be discussed.

If the vaginal pool when submitted to the microscope contains no spermatozoa, alive or dead, the probability is strong that the man is aspermatic and this should then be confirmed by direct examination of the semen as obtained by expression or from a condom specimen. Such aspermia may be merely temporary and is frequently neither permanent nor hopeless; but into the prognosis and treatment of aspermia and azoospermia I do not here propose to enter. If the vaginal pool contains an abundance of spermatozoa which are either dead, or at best feebly motile, at the time of a reasonably prompt examination, the character of the vaginal secretion is probably responsible for their death, and should in most cases be altered by treatment; but the importance of the vaginal condition is much affected by the size and position of the os uteri. There are not a few cases of widely opened os, with normal cervical secretions, in which a reasonable number of living spermatozoa succeed in entering the cervix in spite of a hostile vaginal secretion, that is, before it takes effect on them. If they succeed in entering the cervix in sufficient numbers and with sufficient vitality to be found later in the uterine mucus the condition of the vaginal secretion is of course of but little importance. If, however, as is frequently the case, spermatozoa are found, in an apparently normal cervical secretion, either dead or in a condition of limited vitality while the majority of their brethren have been killed by a hostile vaginal secretion, it becomes probable that even the most successful ones were largely devitalized by the latter, and its treatment is of the utmost importance.

Much the same thing may be said of the hostile conditions of the cervical secretion; but it may be remarked, in passing, that it is extremely interesting to see how often actively motile spermatozoa may be seen to progress across the field of the microscope in a cervical secretion of grossly normal appearance, until they come in contact with some clump of pus cells which is evidently tied together by sticky secretion, with which the tail of the spermatozoon becomes entangled. The result then is that he indulges in futile struggles to escape, by the violence of which he may be seen to become exhausted, and in a few minutes gives up the struggle and lies still. This is of course due to the admixture with normal serum of thick inspissated mucus from inflamed cervical glands. In these cases the cervical mucous membrane must of course be rendered normal before impregnation is likely to occur. It may here be again remarked that this is unlikely to be effected to the degree of normality which permits of impregnation, without an intelligent alteration of the size and shape of the os and cervical cavity by a plastic operation, in addition to a curettage and thorough if not repeated disinfections of the mucous membrane.

These conditions as actually seen under the microscope, then, amply demonstrate the reason for the almost invariable failure, in sterility cases, of the mere dilatation and curettage in which the general practitioner so often indulges, not infrequently, too, with results which permanently decrease his patient's chance of fertility under any treatment. At least such has been the result of my observations in this class of cases.

If the uterine mucus contains spermatozoa which have penetrated there and then died prematurely (they should live many hours if not days in this situation), it becomes probable that they have been killed by exposure to the tubal secretions so soon as they have reached the point where those secretions are but little if at all diluted by the secretion of the uterus, and those of the lower portions of the tract through which the spermatozoa have lived. If the uterine cavity contains fairly numerous spermatozoa of high and persistent vitality in a woman who nevertheless remains persistently sterile, the demonstration that her sterility is ovarian is sufficiently satisfactory to be practically useful.

By this means of direct observation of the progress of the spermatozoa through the genital canal, of their comparative vitality at the start and in each stage of their progress, an experienced observer may obtain information of the utmost value. In his interpretation of these facts, however, he must be guided not merely by these results, but by their correspondence with the observed local conditions both gross and microscopic, and by these as checked by his remembrance of all the light gained from the history, and from his study of the general condition of both partners. Otherwise I believe that he will take an unduly narrow view and will be in the long run none too successful in his management of these cases.

Success in diagnosis and prognosis from such complicated observations as these must always be a matter of the personal equation, but with sufficient care and thorough study they become increasingly accurate and often surprisingly so.

The prognosis in individual cases may now be discussed in accordance with the classifications by causations originally proposed.

If the male is azoospermatic the prognosis is that of azoospermatism, which varies with its cause.

If his spermatozoa are either few, abundant but somewhat lacking in motility, or in any other way imperfect, the prognosis which would be derived from the condition of the woman is impaired by just the amount of the feebleness of the male, and though it is usually not hopeless, both elements must be remembered in forming it.

If the spermatozoa are not only abundant but also long tailed, well formed, and active, the prognosis can be made from the condition of the wife alone.

When, in such cases, the only abnormality found is in the character of the vaginal secretion, or in such alteration in combination with a pinhole-sized and badly placed os, the prognosis of fertility under appropriate treatment is that of almost certain success. When, with first class spermatozoa, the abnormality is found in the cervix with an apparently normal uterine body, tubes and ovaries, the prognosis after appropriate treatment is always very good. When, with first-rate spermatozoa, the abnormality is apparently to be found in the uterine body, that is, when the uterine secretion as obtained by the syringe is sticky, or unduly filled with clumps of leukocytes; when the ordinary symptoms of endometritis are present; when the bimanual examination shows the uterus large and soft; but, on the other hand, when a careful bimanual examination under anesthesia satisfies the attendant that there is every probability that the ovaries and tubes are normal, the prognosis under treatment is good. When the abnormality is believed to be slight but existent in both tubes, that is, when both tubes are palpable though not greatly enlarged, the prognosis, though not necessarily hopeless, is not good. When both tubes are grossly diseased the prognosis is, in my opinion, so poor that operation is not justified for sterility alone unless both partners insist on it after full statement of the poor prognosis. When coincidence of all the above methods of examination leads the observer to believe that though one tube is undoubtedly or probably abnormal there is reason to believe that the other tube is normal, the prognosis is again good, after the removal of the affected tube. I have had several most satisfactory successes in such cases, though we must, of course, be always prepared in these cases to find that the second tube is occluded in spite of our belief to the contrary. When the whole genital canal is normal or substantially normal as shown by the result of an inspection and examination under anesthesia, with the support of the presence of active spermatozoa at the fundus, that is, when the fertility is demonstrably merely ovarian, when arrest of development is not present, but the ovaries are either normal or slightly enlarged, the prognosis after conservative operation on the ovaries is thoroughly good. In my opinion such an operation is justifiable under the conditions of today for sterility alone, provided that all the pros and cons have been placed before both parties and that both of them request operation after due consideration of them.

In the far more common cases in which there is an admixture of several of these abnormalities the prognosis must be determined for the individual case by carefully weighing the principles set forth above as applied to the individual combination of circumstances.

The results obtained in the treatment of sterility have long been, and too often are still, proverbially poor. I believe that the reason is to be found in the fact that so many physicians treat these cases from a purely empiric point of view and without any attempt at educating themselves in the special subject of sterility.

In the first place, the importance of an examination of both partners is too frequently overlooked; in the second place the search is too often directed to the discovery of lesions which should create ill health rather than toward the often minor conditions which determine sterility. To judge from my own experience, sterility is about as frequently the fault of the male as of the female, but popular opinion usually places the responsibility for the sterility on the woman, and this popular superstition is too often shared by the profession. I regret to say that my daily experience teaches me that many gynecologists do not hesitate to treat women and even subject them to operations, for sterility alone, with no knowledge whatsoever of the condition of their husbands. I feel bound to confess that in earlier days I have done it myself.

On the other hand, while urologists constantly rail at this weakness of the gynecologic portion of the profession, study of their writings inevitably leads one to the conclusion that too many of them have not plucked the beam from their own eyes. I have seen too many cases in which expert urologists have based their opinion on the sterility of a couple on an examination of the man alone to doubt that this branch of the profession is also often at fault. If the examination of a man shows him to be aspermatic no examination of the wife is necessary until his case has been concluded, but if, as so often happens, spermatozoa are present but are of doubtful excellence, the prognosis of the case must depend on the results of the examination of both partners. In this class of cases the examination of the spermatozoa as taken from the female genitals is of especial value, since it makes it possible to check at one sitting both the urologic and the gynecologic examinations, and to estimate their relative importance.

Nothing is more common than to have a woman referred from a distance unaccompanied by her husband, who is, however, stated by their attendant to be "all right": and then to find that the statement that the husband is normal means merely that he is in general good health and potent, and does not mean that his spermatozoa have been seen. The treatment and more especially the operative treatment of a woman for sterility alone without actual inspection of her husband's spermatozoa is entirely unjustified. It is certainly practically expedient, and probably justifiable, to treat for sterility, even in an operative way, women who have been referred from a distance unaccompanied by their husbands, who present sufficient causes for sterility in their own person, and who bring an authoritative statement that the husband's spermatozoa have been examined and found normal, but the advantages to be gained by the inspection of the spermatozoa in their progress through the woman's genital tract, though not in my opinion essential, are nevertheless so considerable that sterility patients should, whenever possible, come to the specialist accompanied by their husbands.[3]

The case against the profession goes further than this common failure to study the couple as a pair, however. It may almost be said that the usual course of the gynecologist confronted by a case of sterility is to treat it from the standpoint of health and not from that of the relief of sterility, that is, to institute treatment or perform operations, directed to the removal of anatomic or other alterations which he perceives in a woman's genitals, without stopping to consider whether these observed peculiarities have anything to do with her individual sterility or not. It may almost be said that when the average gynecologist fails to detect any cause for sterility he dilates and curets the woman for the sake of doing something. There are of course many men whose conduct of such cases is conscientious and able, but the above description is, I believe, not too strong a statement of average facts, and has in my experience, in part at least, been applicable to the practice of some men who in other departments of gynecology are of recognized preeminence. Such empiric treatment is worse than useless. It too often renders futile, future rational efforts for the relief of the conditions which are actually important in the given case.

I believe it is mainly by reason of these two faults on the part of the profession that the treatment of sterility is so frequently unsuccessful. I believe that when sterilities are, as a habit, managed by the examination of both partners as soon as sterility has become probable and before the woman has been subjected to useless and usually harmful minor treatment and operations, its prognosis will become what it ought to be and what it today is in well-managed cases, usually satisfactory.

321 Dartmouth Street.

ABSTRACT OF DISCUSSION

DR. JOHN O. POLAK, Brooklyn: I wish to emphasize one point in connection with what Dr. Reynolds has said in regard to the fertility of the man. This point should be taken into consideration in every case; i. e., the male's past performances. I always have the man examined not only as to his potency, but as to the presence of evidences of previous infection, because that link—the history of previous infection—has a great influence on his potency.

DR. JOSEPH B. DELEE, Chicago: My associate, Dr. Lespinasse, has been working on cases which I have referred to him, to see if we could not reach a solution of the difficulty presented by those cases in which the husband is well and the wife is well and yet sterility exists. He has worked in the light of the knowledge given us by recent studies in serology. We all know of certain instances in which the husband, after a divorce from the sterile wife, has secured children from another woman, and the wife, on remarriage, has also been fertile by another man. I, personally, have such a case under my present care, having delivered the woman twice after a second marriage, and a physician in Los Angeles having delivered the second wife of this woman's former husband.

Why did not the spermatozoa of the first husband succeed in fertilizing the ovum of the first wife? Lespinasse has found the secretions in different women dissolved the spermatozoa of different men—a sort of immunity reaction. Experiments are being made, but I am not yet able to give the results, since we want to accumulate a sufficiently large number.

When Dr. Reynolds mentioned the change in the local secretions, this is but a step further in the study of the gross symptomatology and pathology of the genital tract. We have got far enough in the study of these immunity reactions that it seems possible we may find the cause of sterility where the husband presents no evidence of disease, has strong, living spermatozoa, and where the wife has no pelvic inflammation or no real surgical pathology of the parts.

The treatment of sterility has been, in a manner, extremely routine, and therefore, unsatisfactory, and women are bandied about from one specialist to another until they lose faith in medical art.

---

[3] A satisfactory examination of a couple for sterility cannot always be concluded in a single office visit. It may not infrequently require a number of visits, sometimes at intervals of several days.

Another point that will explain some of the causes of sterility is the abnormality of the internal secretions. I hesitate to make that statement because it throws us into an immense field that is very dimly lighted by positive knowledge, but I do know cases that have been unsuccessfully treated elsewhere and have been successfully treated by the glands of internal secretion—thyroid and other extracts. In some instances administration of these preparations has been followed by impregnation, especially that type of firm fat obesity, in which the women are round and plump and the fat is hard, almost like firm flesh, and the periods are inclined to be irregular and small in amount. Those cases have responded to combined treatment occasionally.

The use of alkaline douches just before intercourse deserves mention. The husband, as a cause of the sterility, must be always emphasized, and I have found that excessive smoking of tobacco is occasionally a cause of sterility, and that alcohol, even when the spermatozoa are alive and motile, indirectly prevents them from successfully fertilizing an ovum; that workers in arsenic, antimony, and other chemicals, in spite of live spermatozoa are sometimes sterile. Then I have had men who have had syphilis and are sterile, even though the examination of the semen showed motile spermatozoa. The sperm injected into the woman has both a local and a general effect. It has been demonstrated that the spermatozoa not used for fertilization enter the cells of the genital tract and are absorbed into the cell. This is a line of light on the immunal theory. Isn't it possible that a woman can be immunized; her serum so protected against the advent of the spermatozoa that it dissolves them when they come? Perhaps this explains—when the husband or wife has been sent away for six or eight months—successful fertilization. The law of incompatibles thus bids fair to be explained.

Dr. H. O. Pantzer, Indianapolis: His, the anatomist, said that the complexity of the genitalia in the human female is such as to make it, to him, a surprise that woman ever conceives. Regarding the nervous excitability referred to, I have this observation to mention, that women who have delayed menstruation frequently give evidence of a presenile sclerosis of the ovum. These cases are often associated with chronic intestinal auto-intoxication. This interrelation of toxemia and ovarian sclerosis is not surprising when we recall that toxemia strikes essentially at all glandular organs, and in all is followed by withering and sclerotic changes. It is surprising how many cases of spanomenorrhea or amenorrhea are helped by looking after systemic elimination. All will remember the reliance the older practitioners and gynecologists placed on elimination, as evidenced by the free laxative remedies invariably contained in their prescriptions.

Dr. Edward Reynolds, Boston: Some of the points about which Dr. DeLee spoke were omitted in my reading, but were in the paper.

I do not think the bicarbonate of soda routine for the acid vagina is a good thing. The acid nature of the vaginal secretions is, in all probability, merely the most superficial indication of the chemical changes which destroy the spermatozoa. The failure of such treatment in the vast majority of cases is because we only neutralize the acidity and not the other chemical alterations. I am unable to speak as yet of various studies which I have made, and have had made, and am making on the chemical and microscopic character of the secretions. So far as I know, the chemical and microscopic examination of the mixed secretion of the male and the female, as obtained from the female genitals, is, as yet, an entirely virgin field. There have been a number of men who have observed the spermatozoa and their action in those fluids, but the essential point which we cannot yet speak of is the microscopic and chemical examination of the mixed secretions; the establishing of a normal standard and the detection of abnormality. I have learned to recognize certain arrangements of pus cells, and have seen the spermatozoa swimming freely, come into one of those pus cells, tangle his poor little tail in it, stop his progress, thrash, thrash, thrash, and lie dead. You have to reduce that apparently normal cervical secretion. There are dozens of such things that we know nothing of. The question of immunity is a very curious and interesting one but from a practical standpoint on both the question of abnormal chemistry and immunity we must be careful how we determine our action in such cases by subjects that are so little worked out that our knowledge is hardly a gleam in the obscurity of our ignorance.

ALFRED BAKER SPALDING, A.B., M.D.
Professor of Obstetrics and Gynecology, Leland Stanford Junior University, School of Medicine
SAN FRANCISCO

Why an impregnated ovum should implant and develop outside the uterus so relatively frequently in the human species and fail to do so in lower animals is a question the answer to which has been sought through investigation by clinicians and laboratory workers for a great many years. Clinicians agree that ectopic gestation is a frequent abnormality of early pregnancy but vary in their estimates of frequency depending on whether their clinical experience has been gained as a necropsy surgeon, a gynecologist, an obstetrician or a general practitioner. The large number of case reports indicate the frequency with which this condition is met by surgeons, but is too irrelevant to be of aid in discussing the subject statistically. In this paper, a statistical study of a definite number of patients will be made in order to estimate the relative frequency of ectopic gestation to disease in general, to women's disease, to pregnancy and to abortion. The small material presented makes the importance of the subject the sole excuse for presuming to answer these difficult questions.

The necropsy surgeon reports that he frequently meets ectopic gestation because sudden death associated with such a condition requires his services to satisfy the demands of the law. The gynecologist considers ectopic pregnancy a frequent condition because he does not take into account the many ordinary conditions which the man in general practice has treated before referring to him the patient with ectopic pregnancy. The obstetrician considers ectopic gestation a relatively rare condition because, through lack of understanding, the laity are prone to come to him only after the first three dangerous months of pregnancy are passed. It is an odd experience that a general practitioner may encounter several ectopic pregnancies quite close together and then practice for some time without meeting a case.

Formad,[1] who was a coroner's physician in Philadelphia, in 3,500 routine necropsies, found thirty-five deaths from ectopic pregnancy. Michel[2] has reported twenty-six cases of ectopic gestation in 6,000 gynecologic conditions, while Hartz[3] reports 3.4 per cent. of ectopic pregnancy in 1,700 specimens examined in the gynecologic laboratory at Jefferson and St. Joseph's hospitals in Philadelphia. Hennig[4] stated some years

ago that the directors of even large obstetric institutions might never encounter a case.

Although ectopic gestation is discussed in textbooks on obstetrics, no modern obstetrician has, to my knowledge, ventured an opinion of its frequency based on his personal experience. My own experience has been that for ten years, while limiting my practice to obstetrics, I did not treat a case of ectopic pregnancy in private or clinic work, but during the last three years while combining gynecology with obstetrics, I have operated on thirteen clinic patients and on seven private patients for this condition. The clinic cases form the basis for this paper as they were encountered at fairly regular intervals in a comparatively large number of patients.

From July 1, 1912, to May 1, 1915 (the time of writing), 36,668 patients have registered in the outpatient clinics of the Leland Stanford University, School of Medicine. Of this number, 2,955 have been treated in the women's clinic. In the clinic, fairly extensive histories of the patients were taken and a careful pelvic examination made, as well as considerable routine laboratory work started. A presumptive clinical diagnosis was entered on the history as soon as conditions justified such procedure. These facts are mentioned because often the diagnosis of early pregnancy is impossible, and because some patients, so soon as that diagnosis is made, fail to report to the clinic. Many cases of pregnancy abort or are aborted after leaving the clinic, and possibly some cases of ectopic gestation are overlooked. Taking these facts into consideration, it is interesting to note that of the 2,955 patients registered in the women's clinic, 554 were operated on for various gynecologic conditions. Of these, 353 were curetted and the curettings, together with the associated pathology, were studied in the laboratory for obstetrics and gynecology.

From these specimens there have been made seventy-three laboratory diagnoses of incomplete abortion and thriteen diagnoses of ectopic pregnancy, 1,225 of the 2,955 patients were confined by the clinic at or near term, which makes a total of 1,311 known pregnancies and 468 patients operated on who were known not to be pregnant.

The remaining group of 1,176 patients who did not enter the hospital includes undoubtedly some cases of pregnancy, but is composed largely of nonpregnant patients such as come to all clinics for treatment of minor gynecologic ailments, as well as patients past the childbearing period, and a few children. The statistical work with this group is not as accurate as with the hospital group and the proportion of pregnant to nonpregnant patients can be estimated only roughly. Still it is important to include with the known pregnancies a fair number of these doubtful cases. For ten years, I have recorded annually the percentage of pregnant patients that have failed to return to the San Francisco maternity clinic for confinement, and have found that, on the average, 25 per cent. of the applicants do so fail to return. Applying this experience to the present clinical material, 393 of the 1,176 doubtful cases, or 30 per cent. of the number of confinements, have been grouped with the known pregnancies, making a total of 1,704 pregnancies, and 783 have been grouped with the operated patients, making a total of 1,251 nonpregnant patients.

From these figures, it will be seen that we have met ectopic gestation thirteen times in 36,668 patients or once in 2,820 cases of illness such as a general practitioner would encounter in a practice covering the diseases of men, women and children. Thirteen cases of ectopic gestation among 2,955 women with pelvic symptoms, or once in 227 cases such as come to the specialist: and thirteen cases of ectopic gestation among 1,704 cases of pregnancy, or once in each 131 pregnancies!

Considering the pathologic diagnoses which have been made in the laboratory, it is seen that 86, or 5.33 per cent. of the pregnant patients were sent into the hospital because of bleeding, and were curetted. A study of these curettements has shown that thirteen of the 86 patients, or nearly 17 per cent. of possible abortions, were flowing because they were suffering with a misplaced pregnancy.

This does not indicate the relative frequency of abortion to pregnancy, which has been estimated by Taussig[5] as high as one abortion to every 2.3 labors, but will, I believe, call attention to the possibility of

* At operation there was found a leather-like fetus 3 cm. long compressed between a pus tube and the fibrous uterus. The patient survived a tube abortion, which undoubtedly occurred six years ago, associated with an attempted criminal abortion.

† In the laboratory there was found a hematosalpinx containing cartilage cells which, with the history, gave evidence that the patient survived an ectopic pregnancy four years ago, mistaking the conditions for a spontaneous abortion.

confusing ectopic gestation with incomplete abortion and should put the general practitioner on his guard when treating such cases.

Albucasis,[6] an Arabian surgeon of the eleventh century, is said to have first described ectopic pregnancy. For generations the etiology of the condition was little understood, but gradually the idea prevailed that, in many cases at least, an inflammatory condition of the adnexa was the predisposing cause.

Dr. William Campbell[7] accumulated these data and published a monograph which later formed the basis of Parry's[8] work and to whom Lawson Tait[9] gives great credit in discussing the subject.

Lawson Tait[9] said, "I believe it to be more than likely that the real cause of this accident is the coincidence of a set of circumstances the most important of which is the destruction or insufficiency of the ciliary movement." Since Tait made this statement, however, investigators have shown that often the cilia are not destroyed. Moreover, the condition of round-cell infiltration, of destruction of the surface epithelium, of agglutination of the septa of the tubes, of edema and fibrosis, which are frequently present in the ectopic tube, are stated by some pathologists to depend on the condition of the existing pregnancy or the recent rupture of the tube rather than a preexisting inflammation. Careful sections of the tubes also show that in some cases the ovum has lodged in a blind passage supposed to be a congenital abnormality.

Webster[10] states that the ovum always imbeds in müllerian tissue and Huffman,[11] on theoretic considerations, carries his idea farther by stating that the ovum always imbeds, in cases of ectopic pregnancy, in anomalous imbedding areas. While these theories are attractive, they lead away from the clinical idea of inflammation and tend to place the predisposing cause of the condition on an unchangeable hereditary basis rather than on the basis of previous inflammatory affections which are preventable. Moreover, it should not be forgotten that decidual reaction of early pregnancy has been noted in the tissues of practically all the organs of the lower abdomen, including the omentum and the appendix.[12] Leo Loeb[13] recently concludes that guinea-pigs do not have ectopic pregnancy because it is impossible to create in them a decidual reaction outside the uterus. One reason for the frequency of ectopic gestation in human beings undoubtedly depends on the ability of the tissues into which the ovum penetrates to develop decidua, which affords the ovum an adequate soil for development, but this does not eliminate the fact that pelvic inflammations often result in deformities of the tubes, which causes the ovum not infrequently to imbed outside the uterus.

A clinical summary of the cases here reported is presented in chart form and from this it will be seen that the average age, the multigravida, the number of preceding induced and spontaneous abortions as well as attacks of gonorrhea, the period of relative sterility and the microscopic findings all point strongly to the clinical idea of Tait that many of the cases of ectopic gestation trace their etiology to a preceding pelvic infection. It might be added that gonorrhea plays the minor rôle, and that abortion, associated as it so often is with a more or less noticeable attack of salpingitis, is the major predisposing cause for this frequent, dangerous anomaly of pregnancy.

CONCLUSIONS

From a statistical study of 36,668 clinic patients, the relative frequency of ectopic pregnancy is estimated as follows:

General practice	Once in 2,820 cases
Gynecology	Once in 227 cases
Pregnancy	Once in 131 cases
Early pregnancy with hemorrhage (necessitating curettement)	Once in 7 cases

Lane Hospital.

ABSTRACT OF DISCUSSION

Dr. Joseph B. De Lee, Chicago: Ectopic gestation occurs not infrequently in the lower animals, the horse especially, the cow and others. I know an interesting case in a house dog, running for six or eight weeks with symptoms of peritonitis. A roentgenogram disclosed the location of the fetus, an operation was performed, and a happy recovery made. As to the frequency of ectopic gestation, in my early years, in my hospital services everything except the actual delivery of a baby was assigned to the surgeon or to the gynecologist, and therefore, the obstetrician did not get the cases. He was considered perhaps one or two degrees better than a midwife, and of a different sex. This was the only distinction that I could learn. But as I began to assert my rights, and obtained all the obstetric cases, I found that the frequency of extrauterine pregnancy was increased. Perhaps we are losing sight of the point that so-called colics shortly after marriage, sometimes diagnosed as appendicitis, are not infrequently ectopic gestation aborting through the tube. You all know prostitutes' or actress' colic, and occasionally you hear of an actress being carried off the stage in a fainting condition. These are frequently cases aborting through the fallopian tube, and if properly diagnosed would increase the number of ectopic gestations which occur.

Dr. Alfred B. Spalding, San Francisco: I am not very much of a veterinarian and cannot dispute the point with Dr. DeLee about the ectopics occurring in the lower animals, but a great deal of work along this line has been done by others and many of the supposed cases of the ectopics in lower animals have been considered to be due to rupture of the uterus and to a secondary implantation of the ovum in the abdominal cavity.

Also the relation of the tube to the double uterus in the lower animals is different from that found in the human being. Loeb's work was on guinea-pigs. He found that it was impossible to make them have an ectopic pregnancy by any mechanical or experimental means, and they are not supposed to have an ectopic from natural causes. He was able in one case to get a supposed ectopic from a suspected rupture in the tube, which later was found to be a rupture of that part of the uterus which forms the connecting link between the two.

Responsibility in Rural Sanitary Improvement.—Again, this is within the purview of the county health officer. But the broadening of the outlook of the resident of the rural district is not the obligation of one man or one profession. The duty is shared by the church, the sociologist, the teacher, the minister, the welfare worker, in fact by all who bear responsibility because of position or knowledge. Where to begin is a point to be considered by each institution or worker in his own locality, but that each should do his part admits of no discussion.—Oscar Dowling, *American Journal of Public Health*, May, 1915.

STREPTOCOCCUS BACTEREMIA IN ENDOCARDITIS

ITS PRESENCE BEFORE AND DURING THE DEVELOPMENT OF ENDOCARDIAL SIGNS *

JOHN A. OILLE, M.D.
Assistant in Clinical Medicine; Junior Assistant Physician, Toronto General Hospital; Assistant Demonstrator in Pathology

AND

H. K. DETWEILER, M.B.
Fellow in Pathology and Bacteriology

TORONTO, ONTARIO

The frequent occurrence of a bacteremia has long been suspected in certain cases in which blood cultures have always been negative. One has often felt that our blood-culture methods were very imperfect, that we failed to grow an organism when one was present. Rosenow's methods[1] are a decided advance and have placed in our hands means of investigating a large variety of diseases from which may come findings that will change present views of common diseases. The importance and wide range of the pathogenic influence of streptococci will become generally better appreciated and the association of certain diseases formerly often observed is even now being placed on a definite bacteriologic foundation.

In the heart clinic recently established at the Toronto General Hospital, in connection with the general medical outpatient clinic, it was felt that blood-culture methods similar to Rosenow's might well be applied to the investigation of cases of suspected endocarditis since this affection is so often observed in those who have never had rheumatism. It would appear reasonable that all cases of endocarditis are bacterial in origin, that the organism must be present in the blood for long periods at a time and could be demonstrated if our cultural methods were sufficiently perfected.

There was attending the medical outpatient department during the summer of 1914 a girl (the patient in Case 1) whose case had been diagnosed previously in Ward G as one of pulmonary tuberculosis. However, she had no cough or signs of activity and her morning pulse rate was too slow. Yet she had slight fever, the temperature reaching 99 to 99.4 on an average about twice a week. There was then no murmur present. It was this case that suggested the great value of an efficient blood culture. Success along this line has been attained even beyond expectations, so that now cases formerly diagnosed as cases of chlorosis, anemias, indefinite attacks of fever, obscure tuberculosis and especially "nervous breakdowns" are being called endocarditis.

In this method we have a means, second to none other, of diagnosing this interesting and important disease. Indeed in a few cases it has been the only evidence obtained. A bacteremia has been obtained before the onset of the murmur or thrill and in the presence of a normal temperature. Still this technic is not all-sufficient. A culture was taken in a case of endocarditis and general acute serositis following inflammatory rheumatism three or four weeks before death. The culture remained sterile and at necropsy streptococci were cultured from the heart's blood and were even found in direct smears from the spleen. Still, positive cultures have been obtained when scarcely suspected and in rather more than half of the cases investigated.

This communication is a preliminary report of the presence of a nonhemolytic streptococcus, usually, though not always, producing green on blood agar, in the blood in some twenty-six cases of endocarditis investigated by a modification of Rosenow's culture methods during the past six months. The first twenty-three histories are pointed out for special consideration, as most of them represent a class of very mild endocarditis from which it is thought that positive blood cultures have hitherto not been obtained. The last three are added chiefly for comparison as they conform to the variety commonly called in the literature "subacute bacterial endocarditis." Owing to lack of time and the depletion of the staff of the bacteriologic and pathologic departments by the war, in only a small percentage of suspected cases could cultures be made. Seven of the cases were found among the private patients of one of us (J. A. O.), in course of a small general practice in six months. At least as many others have been encountered in the same time in which cultures were not taken for reasons of age or convenience. During the same time only two cases of rheumatic fever have been treated in private practice and the three last cases (24, 25 and 26[2]) are all that have been recognized of subacute bacterial endocarditis of literature type during the same or longer time in both hospital and private practice. If the figures are at all representative, the incidence of a mild form of endocarditis, of the type to be described, must be far greater than the so-called rheumatic endocarditis, or the subacute bacterial (*Streptococcus viridans*) form. The relationship between these varieties remains to be determined.

In April, 1914, Simons[3] published a critical review of bacterial endocarditis of all forms, summing up very well indeed present-day ideas of this disease. He defines it as those cases (1) which are either acute or chronic, (2) are associated with the presence of bacteria in the valvular lesion and (3) in the circulating blood for some (usually a considerable) period of time and (4) are usually of fatal outcome. The idea is current that if organisms are present in the blood, especially in sufficient numbers to be recovered by culture, the case will end fatally in from a few weeks to two years. Simon uses the term bacterial endocarditis to include all organisms (except spirochetes). In this article, however, it is restricted to the type of case so well described by Osler,[4] Libman,[5] Schottmüller[6] and others, under such names as subacute infective or subacute bacterial endocarditis, endocarditis lenta, etc., and caused by a streptococcus variously named *Streptococcus viridans* or *mitis* (Schottmüller), the endocarditis coccus (Libman), modified pneumococcus (Rosenow), saprophytic streptococcus (Horder), and others. It is generally accepted that these terms all apply to the same organism now usually called the *Streptococcus viridans,* though it must be remembered that this term includes a variety of strains of all grades of virulence and having special "affinities" for many different tissues.

Recoveries from the type of *S. viridans* endocarditis described above are very rare but do occur. All recoveries reported can be counted on the fingers. Now if every case of endocardial inflammation (that is, the so-called simple endocarditis, not including the arteriosclerotic form) be bacterial in origin, then all Simon's conditions characterizing bacterial endocarditis should be fulfilled except the fourth. It is certainly safe to predict that all of these twenty-three cases are not going to end fatally in two or even twenty years. It is a well-recognized clinical fact that simple endocarditis can heal and remain healed for a lifetime.

Characteristic symptoms and signs of "subacute bacterial endocarditis" are malaise, fever of all grades, chills, progressive emaciation, weakness and anemia, hematuria, petechiae and other signs of embolism (hemiplegia, etc.) sweats, pigmentation, enlarged spleen and a terminal leukocytosis. Cases 24, 25 and 26 are types of this form of the disease, J. H. (Case 24) dying of emaciation, weakness and anemia, another patient (Case 25) of hemiplegia and one (Case 26) of embolism of the mesenteric artery, followed by gangrene of the small intestine, perforation and peritonitis. The majority of the main series (Cases 1-23) have shown very few of the preceding symptoms (some none), but some have shown just enough to suggest that they might be mild forms (Case 1 especially) and that there is a gradation in severity from the mildest (Cases 15, 7 and 8) to the severest case (Case 1) in which there is anemia, joint pains and considerable fever. Case 4 shows continual fever, nephritis and slightly enlarged spleen. None of the series is characterized by *progressive* emaciation, weakness and anemia. What anemia and weakness has existed has not progressed, indeed has improved, though of course the time of observation has been short. The patient in Case 1 has been under observation one year. Most of the patients look perfectly well, feel well and have no anemia. Hemoglobin below 60 per cent. was found in three cases. Six patients had no fever when the blood culture was obtained or while under observation, except a slight rise for a few days following removal of tonsils. The characteristic temperature appears to be an irregular one, normal all day, often for some days at a time, yet reaching 99 or 99.5 two or three days a week at irregular times of the day. To detect this the temperature must be taken systematically for considerable periods of time.

In seventeen cases the diagnosis was obscure, and was cleared up by the culture. In two or three, tuberculosis was suspected and may be present. T. D. (Case 9) conformed to the textbook description of chlorosis. Some suggested gastric ulcer. Two patients had symptoms somewhat similar to those in mild cases of typhoid (G. F., Case 11, and Mrs. H., Case 16). In fact both had suspicious Widal reactions and G. F. had an enlarged spleen and erythematous spots on the abdomen. But neither had the prostration, coated tongue, or malaise of typhoid, and were ill too short a period of time. E. K. (Case 4) had symptoms of meningitis. But the most characteristic group was that made up of "neurasthenics." Nine complained of fatigue, weakness, depression, irritability, restlessness, crying attacks, etc. "Nervous breakdowns" were common. The preponderance of young adult females in the series was striking. Five were males and eighteen females. Seventeen were between the ages of 16 and 41. Now, when one is consulted by a neurasthenic, the temperature is taken carefully for two weeks, and if fever be present in the slightest degree, or even in the absence of fever, if a history of tonsillitis is obtained, and diseased tonsils and endocardial signs found, a blood culture is taken. Some seventeen neurasthenics have been investigated and a positive culture obtained in nine cases. Seventeen had no cardiac complaint or symptoms when first seen. Eight had, or developed while under observation, a precordial pain, radiating to the left shoulder and down the arm, usually associated with dyspnea and brought on by exertion. This anginal pain in many cases was apparently quite out of proportion to the physical findings and often associated with cutaneous hyperesthesia. Tonsillitis was the usual precursor. In the children (Cases 2, 11 and 22) it was the continuance of the fever after tonsillitis that suggested endocarditis. One waited three or four weeks after the acute attack of tonsillitis before the culture was taken.

A history of tonsillitis occurring in other members of the family was noted in ten cases. In the case of R. F. and G. F., brothers, the mother is subject to tonsillitis and was ill one year with "low fever" at 19. During the last winter the two boys, the mother and the nurse had, each, two or three attacks. In another family the spread of tonsillitis and associated diseases was remarkable. The mother, who has often had nervous breakdowns, had tonsillitis in December. Shortly afterwards the husband had it also, followed in a month by appendicitis, and two or three weeks later, by a second attack with operation. While he was in the hospital the daughter, aged 5, had tonsillitis, after which slight fever persisted for five or six weeks and a pulmonary and mitral systolic murmur developed for the first time. During this interval the baby had a sore throat. About the same time the nurse went home with tonsillitis. While she was away the other maid, the last member of the family, was taken ill with appendicitis and operated on. While she was convalescing the nurse, who had returned, had appendicitis also, with operation. While the little girl was ill with endocarditis the mother's sister came on a visit and two or three days after her arrival she too had an attack of tonsillitis. Several other members of the mother's family have had tonsillitis often, some with endocarditis.

L. M. (Case 7) is interesting, showing the relationship of tonsillitis, endocarditis, appendicitis and gastric ulcer. Chronic appendicitis is blamed for causing gastric and duodenal ulcer. Possibly the real explanation is that both are results of the one infection. None of the series showed cholecystitis but two patients had herpes zoster.

The mitral valve was affected in nearly every case; the aortic in only one or two. In three cases endocarditis was suspected, before the murmur developed. In two the culture was obtained before any murmur could be heard and in two others the only murmur present when the culture was obtained was a faint systolic heard in the second left interspace over the border of the heart. There is some reason for thinking that this pulmonary systolic murmur is very often, more often than is thought, a transmitted mitral murmur, heard over the left auricular appendix. In most cases of mitral regurgitation, when looking at the cardiac action with a good screen, one can see a quick systolic dilatation in the left heart-vessel angle, which suggests a left auricular appendix being dilated with regurgitating blood. This has been seen when only a pulmonary systolic murmur could be heard on auscultation. In three or four cases in which opportunity has been had for watching the development of mitral regurgitation the murmur was first heard in the pulmonary area and later (a few weeks, or in the case of Patient 1 nearly two months) in the mitral area. Moreover, in many cases of mitral incompetency a louder murmur is heard in the pulmonary area, or the space below it than at the apex; and in all cases of mitral regurgitation, observed recently, a pulmonary systolic was present as well as the mitral.

In only one or two of the series was any cardiac enlargement present and that not at all extreme (most in Cases 21 and 6). Four patients had a leukocytosis of short duration (Cases 1, 6, 14 and 19). Six showed signs of nephritis. Five had gastric symptoms. These are often very troublesome and difficult to explain. One had painful subcutaneous nodules on the hands. None had petechial hemorrhages.

Should the presence of the bacteremia alter the prognosis? Probably not, for we have learned from clinical experience that most of these patients get better and live many years. Most of them were too slightly ill to ordinarily be kept in bed. The prognosis of Patients 1 and 21 is uncertain. The latter has a severe anemia and syphilis. Next to these the cases of chronic endocarditis following rheumatism and chorea are most serious (Cases 6, 12, 13 and 14). Patient 6 is a small girl with a fairly well-advanced mitral stenosis. Still, even she should live longer than the two or even three and a half years allotted to the previously recognized cases of subacute bacterial endocarditis.

In treating them, at first in every case the patient was put to bed, with the idea that every one with an active endocarditis should be at rest. Most of the "nervous" patients improved rapidly while in bed, but six did not show much change. Of these six, four have shown improvement since being allowed to be up and about, especially in Cases 3, 10 and 11. E. J. (Case 1) got up against advice and she became no worse. In fact she has lower fever now than she has had for six months. She is the most ill of the series. Hers would be classed as a type of mild case of the subacute bacterial endocarditis of the literature. Eight patients have had their tonsils out while under observation. Of these one (Case 9) improved afterwards. Cases 2 and 10 were uninfluenced. Cases 16 and 22 have been too recent to draw conclusions. The other three patients were so slightly ill before the operation that no difference in symptoms was noted.

The patients were kept in the fresh air as much as possible, encouraged to eat and given iron. Quinin appeared to give benefit in one case. Autogenous vaccines were administered in seven cases. Large doses were worked up to, usually without reaction. Recently it has been customary to start with 500 million streptococci at the first dose and 1,000 million at the second in the effort to obtain a reaction. Two patients with these doses had local reactions (Cases 1 and 5). It is difficult to see any difference in the course of those cases in which the patients were given vaccines, and those in which they were not.

The organisms recovered in the cases cited in this paper are being studied both as to their reactions and by animal experimentation. A detailed report of the results will be given at a later date.

CONCLUSIONS

1. A streptococcus bacteremia is present in the great majority of cases of active endocarditis and probably in all in some stage of the disease.

2. Endocarditis more commonly follows tonsillitis in children and young adult females than is generally believed. Possibly this accounts for the frequency of mitral stenosis in females.

3. This low grade streptococcic endocarditis is much more common than the so-called rheumatic endocarditis.

4. A large number of persons showing symptoms of the neurasthenic type are really suffering from a subacute streptococcic endocarditis.

5. Endocarditis may be active for considerable periods of time without symptoms.

6. A family incidence of tonsillitis and endocarditis (also appendicitis, gastric ulcer and other diseases which are often of streptococcic origin) is of frequent occurrence.

7. The pulmonary systolic murmurs so frequently found in "run-down" and anemic individuals are rarely functional.

On the other hand they usually indicate mitral regurgitation.

REPORT OF CASES

Case 1.—E. J., aged 22, was admitted to Ward G, Toronto General Hospital, June 2, 1914, complaining of general weakness and backache for seven months with dizziness, fainting, dyspnea and palpitation. Her family history is negative. She has had measles, mumps and chickenpox and has been anemic since 17. Two years ago she was confined to bed three weeks with fleeting pains in many joints without tenderness or swelling. The doctor diagnosed grip or muscular rheumatism. From Christmas, 1913, she lost 30 pounds in weight; had morning cough and expectoration, with pains in various joints and throughout the chest till the time of admission. Examination showed some dulness with bronchovesicular breathing found over right apex with no râles. The heart was normal in size, sound clear and distinct. No murmurs. The tonsils were found diseased and removed in July, 1914. On admission, the blood count showed red blood cells 2,500,000, hemoglobin 58 per cent., white blood cells, 8,000. Urine normal. When discharged, July 28, the count showed red blood cells 3,700,000, hemoglobin 75 per cent. Her condition was much improved. While in the hospital the patient's temperature went above 99 five times in fifty-two days and reached 99 on seven other days. The pulse averaged from 70 to 80. The patient attended the outpatient department till December 8. During this time the temperature continued as described above. The pulse was slow in the morning—50 to 60—going to 90 and 100 in the afternoons. During August a systolic thrill in the mitral area was detected. In September a precodial pain developed, brought on by exertion and associated with dyspnea. At the same time there was a suspicion of a pulmonary systolic murmur. On December 8 the patient was readmitted to the hospital (on account of angina pain and a slight swelling of the feet) for a rest. At this time the heart was not enlarged and the presence of a mitral systolic murmur was questioned. A pulmonary systolic murmur on exertion could be heard. On December 18 her temperature rose to 100.5 and from then till now (June, 1915) her temperature has oscillated müller), the endocarditis coccus (Libman), modified pneumococcus (Rosenow), saprophytic streptococcus (Horder), and others. It is generally accepted that these terms all apply to the same organism now usually called the *Streptococcus viridans,* though it must be remembered that this term includes a variety of strains of all grades of virulence and having special "affinities" for many different tissues.

Recoveries from the type of *S. viridans* endocarditis described above are very rare but do occur. All recoveries reported can be counted on the fingers. Now if every case of endocardial inflammation (that is, the so-called simple endocarditis, not including the arteriosclerotic form) be bacterial in origin, then all Simon's conditions characterizing bacterial endocarditis should be fulfilled except the fourth. It is certainly safe to predict that all of these twenty-three cases are not going to end fatally in two or even twenty years. It is a well-recognized clinical fact that simple endocarditis can heal and remain healed for a lifetime.

Characteristic symptoms and signs of "subacute bacterial endocarditis" are malaise, fever of all grades, chills, progressive emaciation, weakness and anemia, hematuria, petechiae and other signs of embolism (hemiplegia, etc.) sweats, pigmentation, enlarged spleen and a terminal leukocytosis. Cases 24, 25 and 26 are types of this form of the disease, J. H. (Case 24) dying of emaciation, weakness and anemia, another patient (Case 25) of hemiplegia and one (Case 26) of embolism of the mesenteric artery, followed by gangrene of the small intestine, perforation and peritonitis. The majority of the main series (Cases 1-23) have shown very few of the preceding symptoms (some none), but some have shown just enough to suggest that they might be mild forms (Case 1 especially) and that there is a gradation in severity from the mildest (Cases 15, 7 and 8) to the severest case (Case 1) in which there is anemia, joint pains and considerable fever. Case 4 shows continual fever, nephritis and slightly enlarged spleen. None of the series is characterized by *progressive* emaciation, weakness and anemia. What anemia and weakness has existed has not progressed, indeed has improved, though of course the time of observation has been short. The patient in Case 1 has been under observation one year. Most of the patients look perfectly well, feel well and have no anemia. Hemoglobin below 60 per cent. was found in three cases. Six patients had no fever when the blood culture was obtained or while under observation, except a slight rise for a few days following removal of tonsils. The characteristic temperature appears to be an irregular one, normal all day, often for some days at a time, yet reaching 99 or 99.5 two or three days a week at irregular times of the day. To detect this the temperature must be taken systematically for considerable periods of time.

In seventeen cases the diagnosis was obscure, and was cleared up by the culture. In two or three, tuberculosis was suspected and may be present. T. D. (Case 9) conformed to the textbook description of chlorosis. Some suggested gastric ulcer. Two patients had symptoms somewhat similar to those in mild cases of typhoid (G. F., Case 11, and Mrs. H., Case 16). In fact both had suspicious Widal reactions and G. F. had an enlarged spleen and erythematous spots on the abdomen. But neither had the prostration, coated tongue, or malaise of typhoid, and were ill too short a period of time. E. K. (Case 4) had symptoms of meningitis. But the most characteristic group was that made up of "neurasthenics." Nine complained of fatigue, weakness, depression, irritability, restlessness, crying attacks, etc. "Nervous breakdowns" were common. The preponderance of young adult females in the series was striking. Five were males and eighteen females. Seventeen were between the ages of 16 and 41. Now, when one is consulted by a neurasthenic, the temperature is taken carefully for two weeks, and if fever be present in the slightest degree, or even in the absence of fever, if a history of tonsillitis is obtained, and diseased tonsils and endocardial signs found, a blood culture is taken. Some seventeen neurasthenics have been investigated and a positive culture obtained in nine cases. Seventeen had no cardiac complaint or symptoms when first seen. Eight had, or developed while under observation, a precordial pain, radiating to the left shoulder and down the arm, usually associated with dyspnea and brought on by exertion. This anginal pain in many cases was apparently quite out of proportion to the physical findings and often associated with cutaneous hyperesthesia. Tonsillitis was the usual precursor. In the children (Cases 2, 11 and 22) it was the continuance of the fever after tonsillitis that suggested endocarditis. One waited three or four weeks after the acute attack of tonsillitis before the culture was taken.

A history of tonsillitis occurring in other members of the family was noted in ten cases. In the case of R. F. and G. F., brothers, the mother is subject to tonsillitis and was ill one year with "low fever" at 19. During the last winter the two boys, the mother and the nurse had, each, two or three attacks. In another family the spread of tonsillitis and associated diseases was remarkable. The mother, who has often had nervous breakdowns, had tonsillitis in December. Shortly afterwards the husband had it also, followed in a month by appendicitis, and two or three weeks later, by a second attack with operation. While he was in the hospital the daughter, aged 5, had tonsillitis, after which slight fever persisted for five or six weeks and a pulmonary and mitral systolic murmur developed for the first time. During this interval the baby had a sore throat. About the same time the nurse went home with tonsillitis. While she was away the other maid, the last member of the family, was taken ill with appendicitis and operated on. While she was convalescing the nurse, who had returned, had appendicitis also, with operation. While the little girl was ill with endocarditis the mother's sister came on a visit and two or three days after her arrival she too had an attack of tonsillitis. Several other members of the mother's family have had tonsillitis often, some with endocarditis.

L. M. (Case 7) is interesting, showing the relationship of tonsillitis, endocarditis, appendicitis and gastric ulcer. Chronic appendicitis is blamed for causing gastric and duodenal ulcer. Possibly the real explanation is that both are results of the one infection. None of the series showed cholecystitis but two patients had herpes zoster.

The mitral valve was affected in nearly every case; the aortic in only one or two. In three cases endocarditis was suspected, before the murmur developed. In two the culture was obtained before any murmur could be heard and in two others the only murmur present when the culture was obtained was a faint

June 5: During all of this time his temperature was normal with the exception of two days following the operation when it reached 99.5 and 100 respectively.

CASE 6.—Miss B, aged 8½, weighed 3½ pounds at birth. At 2½ years she had adenoids and otitis media. The adenoids were removed. The heart was normal. In June, 1912, she began to be restless at night with night terrors, which lasted six weeks. Then she began to have nausea and pallor in the mornings with no elevation of temperature. On the fourth day her heart was said to be badly diseased. After three weeks there was marked muscular twitching and loss of voice, said to be chorea. She was confined to bed until the end of October. All of this time no record of temperature was kept. In the beginning of November she was allowed to be up and in December the doctor said the heart was as well as ever it would be. In February, 1913, she contracted a catarrhal cold and looked very tired. The doctor found the pulse rate 145 and the heart violent and irregular in action with a low afternoon temperature. Twitching movements of muscles again appeared. In a period of improvement in March the tonsils were removed. She was confined to bed until June 5 but was not allowed to walk until September, at which time the heart was apparently normal in size and no murmur could be made out. In October, after strenuous exercise, a soft systolic murmur could be detected.

In December 1913, she had a slight catarrhal cold. Between this and Easter, 1914, she had two colds with high temperature, but was only confined to bed for two or three days. The heart seemed unaffected. The child continued active and strong except in September, 1914, when abdominal tenderness led to a reexamination and it was stated that no abnormal condition could be found in the heart. In November she was examined again for abdominal pain. At this time there was a slight systolic murmur. In February, 1915, she had a catarrhal cold, contracted from the mother, marked sore throat, glandular enlargement, high temperature, and a leukocytosis of 19,000.

The heart was dilated, very rapid, with a harsh presystolic and systolic murmur. In April a Rosenow blood-culture gave a plentiful growth of *S. viridans*. Leukocyte count, 11,000. At this time quinin—3 grains four times a day—was administered. The temperature gradually fell to normal in about two weeks' time. Vaccine 1,000,000,000 increased to 2,500,000,000 every fourth day. Only once was there local reaction. The pulse rate ranged from 88 to 110. On June 10 the child was allowed to get up. The pulse rate increased only 5 to 10 beats during the first three or four days, then remained about 100 until the present date. The child is up and playing about, six hours a day. At no time throughout the course has there been found any abnormal urinary secretion.

CASE 7.—L. M., aged 24, a nurse girl, entered Ward G for investigation of symptoms of indigestion consisting of heartburn and nausea. She also complained of weakness and fatigue. Her mother died of heart disease at 37. The patient's tonsils were removed incompletely (?) ten years ago. She had appendicitis with operation six years ago; tonsillitis two years and 1 month ago; two attacks of gastric ulcer twelve and nine months ago. Has vomited "coffee grounds." The organs are normal except the heart, which shows a rough mitral and pulmonary systolic murmur with no cardiac enlargement. The tonsils were badly diseased. Red blood cells, 4,800,000; white blood cells, 8,000; hemoglobin, 75 per cent. Urine normal. Test meal and bismuth meal revealed nothing abnormal. Tonsils were removed May 23 and showed marked disease. Cultures from the tonsils and the Rosenow blood-culture showed *S. viridans*. The temperature reached 99 occasionally. The patient felt perfectly well after a week's rest in bed.

CASE 8.—E. B., aged 25, a music teacher, was referred from Dr. L. on April 23, 1915, for investigation, on account of two attacks of iritis lasting three weeks. She complained of being run down, tiring easily, headaches and some depression. Has had headache over the right eye all her life. She was operated on for fibro-adenoma five years ago and hernia eight years ago. One month ago she had tonsillitis. Her sister is subject to tonsillitis. The mother died of appendicitis. On examination the patient, a well-nourished woman, did not appear ill. The heart showed no enlargement or thrill. There were systolic murmurs in the mitral, pulmonary and aortic areas. Spleen slightly enlarged, by percussion not palpable. Other organs normal. Red blood cells, 4,900,000; white blood cells, 6,600; hemoglobin, 85 to 90 per cent. Crypts of the tonsils contained an exudate. The temperature was normal. A blood culture on April 28 showed profuse growth of streptococcus. The tonsils were removed May 31. Cultures from the tonsils showed a similar strain of *S. viridans* to that obtained by blood culture. After six weeks' rest she feels perfectly well. Her temperature continues normal.

PROSTATECTOMY MISTAKES AND FAILURES *

GEORGE S. WHITESIDE, M.D.
PORTLAND, ORE.

Having in mind some of my own failures and believing we can often learn more from the consideration of mistakes than from successes I sent out a questionnaire to a number of my friends, having for its object an inquiry into prostatectomy and the ultimate results of operation. Many did not contribute to this series because, as Dr. Schmidt put it, "If my case histories answered these questions I would write a paper of my own." Some others who did reply had evidently guessed at many of the questions to such an extent as would render the whole inquiry misleading if their cases were included. Therefore I take the work of thirty-four surgeons who give fairly good notes on 1,423 cases. These include my own. Many names will not be mentioned for various reasons.

Let us consider the errors in order to discuss their cause and the avoidance of them. In 1905, before this association, I read a paper publishing the fact that many surgeons had an average mortality of 20 per cent. in prostatectomy and only about 30 per cent. of good results. This paper was productive of great good, since Hugh Young in 1906 produced a splendid critical analysis of his cases in order to prove that when properly performed the mortality of prostatectomy is low and the results good. Even this monumental compilation has not accomplished all the missionary work necessary, as can be seen from the present series of cases. Young[1] sets forth the fact that when a prominent surgeon publishes a series of successful cases he incites many to try to imitate his success without proper instructions in his operation or understanding of the procedure or of the dangers to which he subjects his patient. The object of my paper ten years ago was largely to call to the attention of the surgical world the need of some method by which patients' lives or comfort may be safeguarded without injustice to any surgeon. In this present series about half the surgeons contributing, operating on more than half (820) of the 1,423 cases, are men of unquestioned training in prostatectomy by either the suprapubic or perineal routes. A comparison shows the mortality of the operation in the hands of these men to be less than 3 per cent. while in the hands of other surgeons of less experience in prostatectomy (although perhaps equally or more skilful in other forms of surgery) it is 26 per cent. Now is it right in these modern days to sit smugly by without comment, while patients are sacrificed to the ambition of men unprepared to do this operation properly? I do not speak of novices or immature boys just out of the medical school, but of men undoubtedly able to be of great help to their patients in other ways but who are not sufficiently experienced in this operation. There are four excellent general surgeons contributing each a small number to this series who are the exceptions that prove the rule. These four men have had only a few cases of prostatectomy, but no mistakes or failures or even a justifiable death can be quoted against them. I believe this exception proves that there is nothing mysterious about good results in prostatectomy; that after proper diagnosis and a well-considered operation these results are obtainable by any really good surgeon by methods similar to those used in other major operations.

* Read before the Section on Genito-Urinary Diseases at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

[1] Young: Hypertrophy and Cancer of the Prostate, Baltimore, Johns Hopkins Press, 1906, p. 2.

Let us consider for a moment the matter of diagnosis. In this critical analysis of a series of cases, methods of diagnosis can not be described in detail. It would seem unnecessary to call attention to the fact that a correct diagnosis is important before prostatectomy but evidently many otherwise careful surgeons consider the diagnosis of this condition so easy that they do nothing more than guess at the problem presented to them. Stricture of the urethra, spinal neuroses, condition of kidneys and other organs are frequently slighted or missed altogether in their examination. Even the most experienced operators occasionally overlook a case of prostatic or periprostatic cancer. In our present series, taking only the cases reported in which the surgeons have evidently tried to differentiate between hypertrophy and cancer, 7.3 per cent. of these patients were, in ultimate analysis, found to have cancer. This is a considerable percentage. It is worth reflection before operation.

Dr. A. says he operated in a case of cancer which proved very extensive. Result, urinary fistula which could not be closed before the patient died. It is possible that a thorough examination might have demonstrated this case to be inoperable and the patient had better have been left to die in peace. As a matter of diagnosis too, it is well to so examine patients that a wise choice of the suprapubic or perineal routes will facilitate the removal of the gland with best ultimate results. This is not the time or the place to open a discussion between the operators using exclusively the high or the low procedure. Many surgeons believe the high operation more suitable for one class of cases and the low for another. There is so much of the personal equation in this that universal agreement never will be possible. Watson of Boston attributes two deaths to "applying the perineal operation to very large prostates, one of them weighing 12, the other 10 ounces, after prolonging, by the effort, the operation, being forced to have recourse to the high operation and losing both patients from hemorrhage or shock, largely because of failure to choose the high operation in the first place." In a case of my own not long since the converse was true. The prostate was small but obstructing. The bladder contracted. In the suprapubic operation I accidentally opened the peritoneum and was finally obliged to have recourse to a perineal incision in order properly to enucleate the gland. Had I chosen the perineal route for this case in the first place no mistake would have occurred. This patient eventually recovered, but the operation was more severe than was necessary. L. Davis of Boston also reports to me having once accidentally opened the bowel in a suprapubic section. Possibly the patient had a small contracted bladder as mine just mentioned did.

In regard to the perineal operation it is only fair to note that a rough tearing-away operation, through a too small incision without much regard to the anatomy of the perineum, causes many absolutely unnecessary results such as rectal fistula and injury to the vesical sphincter producing incontinence. In our present series we note fourteen cases of rectal fistula and twenty-four of postoperative incontinence, all in perineal operations. I believe Young is right when he states that these mistakes are absolutely avoidable by doing an anatomically correct dissecting operation, under the guidance of the eye, and in absolutely condemning a blind manual enucleation of the prostate through a short perineal wound. Watson says, further, that "injury to the rectum is caused usually by pressure on the upper surface of the gland either when enucleating or when withdrawing it." In two cases in this series a rectal fistula was caused by passage of instruments, in one case a rectal tube and in another a urethral catheter. In this connection also one surgeon mentions a case of death from perforation of the sigmoid flexure by a rectal tube ten days after operation. These three accidents have nothing to do with prostatectomy, perineal or otherwise. Two cases of fatal hemorrhage, caused by passage of a rectal tube a day or two after suprapubic prostatectomy, present to us the danger of postoperative rectal instrumentation either for lavage or for the introduction of salt solution by the drip method.

In determining the probable chance of a patient before operation, perhaps the one most important examination is to ascertain the functional activity of the kidneys. This is unfortunately not so frequently done as it should be. Failure to do so accounts for the high mortality mentioned against the occasional prostatectomist and many general surgeons in this series. Uremia, so-called, after prostatectomy, should usually be labeled renal insufficiency. A sufficient number of tests of renal function should be made to indicate to the surgeon the gravity of the risk in each case. In cases in which absolute or even repeated retention of urine exists, the relief of operation should not be withheld because of the increased risk due to renal insufficiency, but a knowledge of the results of tests will warn the surgeon to safeguard renal function in every possible way. Dr. P. reports two patients dying of renal insufficiency within a few days after operation. This in spite of the fact that this surgeon is a skilful cystoscopist and might easily have ascertained the renal condition before operation, which he did not do. He says he has depended too much on clinical symptoms without a thorough cystoscopic and renal function examination before operation. Consequently his mortality was 30 per cent. Dr. L. had two deaths from uremia immediately after operation. He had not ascertained the functional activities of the kidneys. Some advocate two-stage operations although it has not been proved that a lower mortality results in consequence. Whether to operate immediately or to delay while medicinal and mechanical means are employed to improve the patient's general and renal conditions or whether a preliminary drainage operation is indicated are matters of grave concern, allowing for exercise of rare judgment guided by experience. In this connection must be mentioned the choice of an anesthetic when the kidneys are insufficient. Spinal anesthesia is probably safest. Perhaps it is safest in every case, but certainly it is so in the presence of chronic nephritis. Examination of the heart, blood pressure and lungs from the point of view of the surgeon rather than from that of the physician will eliminate many deaths from "shock" and will materially aid in the choice of the anesthetic. It would be well if all bladders could be examined cystoscopically. Unfortunately this is not always possible. The age of the patient, his mental attitude toward the proposed operation and the size of the obstructing tumor often prevent such an examination.

There is a condition which leads to unsatisfactory postoperative results which may be cystoscopically discovered but is rarely even guessed at without cystoscopy. This is the existence of vesical diverticula. Several contributors to this series mention them as the cause of postoperative residual urine (amounting in a few cases to almost complete retention), and diverticula are frequently responsible for an incurable chronic cystitis with or without calculi. Some say they do not wish to include such cases in an analysis of postoperative results. They should be included, because, if the prostatectomy is undertaken with a full knowledge of the presence of a diverticulum, then the added risk of an unsatisfactory result is carefully considered in connection with the other features of the case, or if the diagnosis is so incomplete that the presence of a diverticulum is not known before operation, then both surgeon and patient have accepted the chance of operation admitting of failure if a faulty guess has been made. Dr. G. considers postoperative cystoscopy important for the purpose of detecting mucous-membrane flaps which may close the vesical outlet like a valve. Cystoscopy may be done advantageously through the wound. In suprapubic cases this is easy. In perineal ones the patient must be in the extreme Trendelenburg or knee-chest position.

Diabetes is a not infrequent complication observed before operation. From a statistical point of view one would not choose to perform prostatectomy in the diabetic. Unfortunately, urinary retention or hemorrhage or pain frequently forces the surgeon to accept the increased risk in order to save life in spite of the probable unsatisfactory end-result.

Squier[2] believes the average duration of life, after the habitual use of a catheter is begun, to be less than three years. We each probably have in mind many exceptions to this but for the sake of argument we must place some limit. If three years is the average then prostatectomy undoubtedly offers to the average sufferer an added period of comfort in his old age in spite of the fact that some will afterward complain of pain, partial retention or other symptoms almost or quite as troublesome as those for which the operation was undertaken. In the present series this number was only 19 per cent. in the whole series and very much less in the cases reported by the best prostatectomists. Probably skill, judgment and large experience reduce the number of unsatisfactory after-results to about 7 per cent. instead of 19 per cent. as in this series, or 30 per cent. in my series of ten years ago. One surgeon writes that he "supposed everyone had none but successful cases" except himself.

F. S. Watson writes me:

> I am very glad to supply such information as my subsequent knowledge of my patients upon whom I have done prostatectomies permits. I lost sight of almost all the patients operated upon at the hospital relatively soon after they were discharged. Of the private patients who numbered about seventy I lost sight of a good many also. I cannot, therefore, regard the data I am sending you as at all complete. The same may be said of most of our surgical practice and that is the trouble with the statistical compilations of data concerning late results of our work. We do not know really just what proportion of them we can regard as actually cured in the strict sense of the word, or how many have suffered relapses, or failed to gain complete relief, etc. Hence the fallacies that are so often connected with statistical work. We rarely have the whole of any of our experiences, and knowing the whole might lead to very different conclusions.

M. Krotoszyner says:

> It is to be assumed that patients in whom the result was not entirely satisfactory might have gone elsewhere for further treatment, and I cannot, therefore, give you data about these cases, but those whom I see off and on and whose whereabouts I am able to trace for years after the operation, are apparently well and without urinary disturbances.

Dr. W. writes:

> Important mistakes resulting disastrously include two operations on patients in extremity. I would better have drained these cases through a ureter catheter passed into the bladder through a suprapubic troca cannula. Both died of uremia. The operation in both cases was short.

Dr. T. "wishes he had not operated upon a case of simple hypertrophy because the patient had frequency, pain and 8 oz. residual several years after operation." He also did prostatectomy in two unrecognized malignant cases. Both patients died within a few months.

Dr. X overlooked a diverticulum of the bladder. For this he later did a second suprapubic section on the same patient. He operated in one case of "atonic bladder" (etiology not stated) and in this case the patient still leads a catheter life.

Dr. B. says he considers prostatectomy ill advised in cases of known prostatic cancer. He had two such cases which he afterward wished he had not touched. Both patients died within two months after operation.

Dr. XY "used chromic catgut deep in perineal wound. Later an abscess formed which opened itself into the rectum. This urethro-rectal fistula never has closed."

It is generally a mistake to be in a hurry before, during or after operation. Insufficient preoperative preparation, inexact diagnosis, hasty judgment as to route or time to operate are only equaled as mistakes by too great haste during operation and lack of skilful care afterward. Prostatectomy, dealing as it usually does with unsound old men, to be successful should have every factor in its favor. The surgeon should be an experienced one and should carefully study his cases. The patient is best cared for in a well-equipped hospital and the operator should personally supervise the after-care of the patient, at least until he is up and about and has regained some of his strength. If these precautions before and after operation are followed the end-results will be generally satisfactory and the mortality low.

Journal Building.

ABSTRACT OF DISCUSSION

Dr. Granville MacGowan, Los Angeles: It has been specifically emphasized on the medical profession that these operations must be performed rapidly. I am a reasonably slow operator yet I do not know of anyone who has a lower percentage of deaths than I have had. The percentage has been so low that I have been afraid to publish it. It is not often necessary to perform the operation of prostatectomy rapidly. One should take the time necessary to do what one intends to do thoroughly. The patient should be well prepared beforehand and well cared for afterward; then he will live and be comfortable. That is a point the essayist has brought out.

In every community are crippled old men who have been operated on rapidly for enlarged prostates without having their obstructions removed. Within the past three months I have seen two such people who were operated on in two of the very best clinics in America. They were operated on very rapidly but they still have their prostates. One paid $5,000 to have his removed but he has a beautiful intravesical growth, and lives a catheter life because he cannot get up courage to be operated on again.

Dr. A. B. Cecil, Los Angeles: The importance of ascertaining the function of the kidneys by the use of the phenolsulphonephthalein previous to operation, should be emphasized. I have used this test very extensively from the time it was first introduced and it undoubtedly gives in many cases data which cannot be obtained in any other way. I have heard the criticism that the excretion of phenolsulphonephthalein has been found to be relatively high and yet the patient died of uremia following prostatectomy, and that another recovered when the excretion of phenolsulphonephthalein was relatively low.

It must be remembered that phenolsulphonephthalein gives us only kidney efficiency but does not tell us how much work the kidneys have had to do. The patient with a low kidney efficiency may be better able to stand operation than a patient with a relatively higher efficiency, because by prolonged drainage, or because of low metabolism, he may not have retention of toxic products in the blood. So that not only must we determine the efficiency of the kidneys, but where this is low, retention should be suspected, and should be determined by cryoscopy or blood urea.

Dr. G. Shearman Peterkin, Seattle: I believe thoroughly in what Dr. Whiteside says. The important thing is that you should operate slowly. One of the advantages of operating slowly is found in spinal anesthesia. When you give a patient a spinal anesthetic it is going to last from three-quarters of an hour to an hour anyway, so what is the use in hurrying. You will not get any better results. You can take your time with spinal anesthesia in this operation when you cannot in other forms of anesthesia.

I want to speak of the diverticulum. In Seattle when we undertake these operations, after catheterizing the patient once, we inject a 2 per cent. silver iodid solution, then take a roentgenogram of the patient lying on his back, or best of all, lying on his stomach, with a tube up against the glutei. You will be surprised how many diverticulums you will see and how many bladder trabeculae you will see. It is even more advantageous than your cystoscopic examination, when you show your patient the diverticulum on the roentgenogram, because he knows then that you know what you are talking about and he is satisfied. If you simply tell him it is there, he may perhaps question your diagnostic ability.

Dr. L. W. Bremerman, Chicago: I think the two most important features in Dr. Whiteside's paper relative to the net results in prostatectomy are brought out in his remarks regarding the preliminary treatment and postoperative treatment. I think the operative procedure is the simplest part of the whole affair. I think most of us are too prone to see our patient today and operate tomorrow, without having made the proper functional tests, and how could it be otherwise than to expect that in a fairly large number of the cases the end-results will not be good. We should take our patients and study them carefully and get the general condition of the patient in proper shape for operation, and then proceed with the operation, and follow it with proper subsequent treatment, which may differ in the minds of many surgeons, but which should always be carried out to some extent. We are so ready to discharge our patients as cured when the abdominal wall heals up, and there is no leakage from the suprapubic or infrapubic wounds. We call our patients well. It is wise to keep those patients under observation for weeks, and discharge them from observation only when the bladder is clean.

The feature Dr. Peterkin brought out relative to a Roentgen-ray examination of his cases is an excellent one, and in all cases the genito-urinary surgeon should have the best possible means of diagnosis. I believe that the proper equipment of a genito-urinary surgeon's office today should include a Roentgen-ray apparatus, and every case should have roentgenograms incorporated as a part of the examination.

Dr. J. I. Butler, Tucson, Ariz.: To avoid, especially in the perineal method, a complication spoken of by Dr. Whiteside, that is, rectal fistula, I have been in the habit of employing the simple procedure of divulsing the sphincter ani as practically the first step of the operation. The object and result of thus relieving rectal pressure is obvious. I think this procedure valuable, and make the suggestion here because I have not seen it in print or in other clinics than the ones I have been connected with. It is carried out just as in hemorrhoid or fissure operations. Of course the levator ani muscle is also sectioned across in front. This permits the use of the Murphy drip in postoperative treatment.

Dr. Hiram R. Loux, Philadelphia: One point of interest in Dr. Whiteside's paper is the postoperative treatment by the drip method of irrigation. That method we have used in our clinic for quite a long time, and it occurred to us that the oozing which follows along the margin, or follows prostatectomy, is positively kept up persistently by the continuous irrigation. The question might be well discussed as to what advantage one really derives from the continuous irrigation. Recently, I talked with Dr. Young and I brought up the question. He told me that he was not irrigating as much as he did some years ago. I have found that the trouble from oozing proceeds for a period of eighteen to twenty-four hours following the removal of the prostates, and that by stopping the drip method of irrigation the clots properly form, instead of being washed away. This continual oozing causes a depression of the patient to some degree.

Dr. George S. Whiteside, Portland: In regard to Dr. Simpson's discussion, some of us who live in the far west do not have the advantage of the Johns Hopkins Hospital and urea blood tests convenient to our hand, and it seems to me that almost the same results can be obtained by the ptyalin test in the urine, and the Tycos blood pressure apparatus.

Dr. Peterkin has brought out a very valuable suggestion that I had entirely forgotten about. He told me about it before. Dr. Bremerman spoke of preoperative and postoperative treatment. It seems to me that is exactly why the real up-to-date genito-urinary surgeon has better results in prostatectomy, on the average, than the general surgeon; because of the fact that he does pay attention to preoperative treatment and postoperative treatment.

Dr. Bremerman is quite right. We should not lose sight of the patient too early. In this series of cases that I have quoted here a very large number of the men did not know whether their patients had residual urine two years afterward or not.

Dr. Butler spoke of rectal fistula and the stretching of the sphincter. Stretching the sphincter does not help in those cases in which the fistula is of mechanical origin, caused by punching through into the rectum at the time of the operation, either with the finger or with some instrument.

Dr. Loux spoke of a postoperative irrigation treatment. I may have misled him on that. I did not say that I did any irrigation after prostatectomy. I do not irrigate them at all for at least two weeks. Convalescence is more satisfactory without lavage than it used to be when frequent washing was the rule.

VERUMONTANITIS *

W. J. PENNOCK, A.B., M.D.
SPOKANE, WASH.

Symptoms ascribed to inflammation of the verumontanum were noted as early as 1839, when Baxter stated that many patients were seen suffering from frequency of urination and a violent throbbing or spasm on passing the last few drops of urine, and that he believed these symptoms to be due to an affection of the mucous membrane in and about the verumontanum.

The veru as an anatomic entity was not recognized by the anatomists, who gave hazy and inaccurate descriptions, Gray, for instance, stating that the verumontanum is a narrow longitudinal ridge formed by an elevation of the mucous membrane and its subjacent tissue — 8 lines in length by a line and a half in height. The sinus pocularis, he describes as a culdesac, one-fourth inch in length, projecting backward in the substance of the prostate behind the middle lobe. The erroneousness of this description was rendered evident with the advent of urethroscopy, but it remained for Rytina to demonstrate the actual gross and histologic anatomy of the gland.

Embryologically the veru is developed from the united lower ends of the atrophied müllerian ducts, which explains the origin of its glandular tissue, and it is in derivation homologous with the uterus and vagina.

Fig. 1.—Section through lower portion of sinus pocularis showing invaginating processes. From photomicrograph.

Rytina has differentiated the organ into a central glandular and a peripheral stromal portion, the glandular portion, consisting of groups of glands showing numerous intra-acinous proliferations, and these infoldings are composed of several layers of epithelial cells, in type varying from columnar to squamous. The peripheral portion is made up of a fibrous-tissue stroma with an occasional glandular acinus and the organ is encapsulated at its base with dense bands of fibrous and elastic tissue. Much eleastic tissue was demonstrated in both peripheral and stromal portions.

PATHOLOGY

There may be simple hyperemia or an edema of the veru and the mucous membrane about and notably posterior to it. The veru may be evenly distended until it practically fills the lumen of the urethra, or smaller, with its surface showing small cysts or ulcerations. In pyogenic cases purulent material may protrude from between the swollen lips of the utricle and in these cases pus often is expressed from the orifices of the lateral lobe prostatic ducts in the prostatic sinuses on each side of the veru. In the acute cases, usually, the inflammation of the veru is only part of the general hyperemia and edema of the prostatic mucosa. In the chronic cases, the surrounding mucous membrane is nearly normal, while the veru is clearly defined, hypertrophied, firm, infiltrated and fibrotic. Michailoff reports cases of calculi protruding from the utricle. Microscopically, Rytina has studied only the infective type of verumontanitis. He finds the essential lesion in these cases to be a submucous and periacinous round-cell infiltration. He also demonstrated in serial sections the infection traveling the entire length of the sinus pocularis.

As I have not felt justified in removing the entire organ in any nonpyogenic case, I have not been able to get sections of the complete gland for examination. Specimens removed by rongeur in the line of treatment comprise necessarily only the hypertrophied upper portion, and show merely hypertrophic changes. It is desirable that we should have sections through the glandular portions to demonstrate if any adenomatous change is present.

ETIOLOGY

Infection by pyogenic organisms, while fairly frequent and probably a necessary concomitant of prostatitis and vesiculitis should not be emphasized as an etiologic factor, as the infection of the veru is less important than the infection of either prostate or vesicle, impossible to eradicate until the subjacent infection has terminated, and is liable to withdraw our attention from the more important noninfective cases. Neisserian infection is undoubtedly common and it is worth noting that the veru may become infected by a descending infection from a pyelitis without definite involvement of the bladder, and the patient's most distressing symptoms may be due to the verumontanitis.

There are many etiologic factors in the nonpyogenic cases.

1. Coitus interruptus is a fairly common cause. My records force me to believe the practice to be more general than we have thought and I now embody the question in all case histories. Obrowski believes we should regard as causative factors any deviation from the normal sexual act that provokes a rapid fall of the curve of orgasm, as by these the automatic reflex contraction of the dilated blood vessels is interrupted, preventing the normal return of the vessels to their collapsed condition of rest. The repeated disturbance of the normal curve causes a lowering of tone of the local blood vessels, resulting finally in their remaining in a state of semidilatation; the hyperemia thus induced being the first stage of inflammatory change. If these partially dilated and relaxed blood vessels are irritated by protracted repetition of the sexual act, a paresis of the vascular muscle results, and the unphysiologic overstimulation produces an eventual paresis of the spinal innervation center, the function of which is to change the condition of the vascular spaces from

---

* Read before the Section on Genito-Urinary Diseases at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

that of the maximal dilatation, intended for a short time, to the state of normal quiescent contraction.

2. Ungratified sexual desire, as exemplified by persons allowing their passions to be aroused by intimacies, while refraining from the sexual act, falls in the same class as coitus interruptus. The maximal dilatation of the blood vessels is maintained for a greater length of time and a longer relaxation and consequently a more pronounced stasis is produced.

3. Masturbation is so evidently unphysiologic that I simply mention it to call attention to the fact that after an inflammation has been produced by the practice, the continual irritation of the inflamed veru may make it almost impossible for the patient to break himself of the habit. I desire to emphasize the need of examination of the veru in all cases of onanism in the adult. Cole states that often masturbation is the cause rather than the result of verumontanitis.

SYMPTOMATOLOGY

The symptoms of verumontanitis may well be divided into those referable to the urinary and those referable to the genital systems, the individual case usually showing symptoms referable to only one system.

1. Urinary symptoms:

(a) Urinary frequency: This varies from urination every fifteen to thirty minutes, with a nearly constant interval desire to urinate, in the acute cases, to every one and one-half to two hours with no interval distress in the chronic cases, in which annoyance may be caused only by interrupted sleep.

(b) Urinary precipitancy.

(c) Burning sensation in the deep urethra, sometimes referred to the end of the penis. This may occur only for a few minutes following urination, may be constant or, quite often, may gradually increase during the urinary interval, forcing the patient to urinate in the endeavor to alleviate the sensation. I had one patient who had this symptom for a few hours each day, the remainder of the twenty-four hours his condition being entirely normal.

(d) Terminal tenesmus is present in the acute cases.

(e) Hematuria is present in the acute and subacute cases, varying from macroscopic blood in all three glasses — a few drops of blood extruded at the end of urination — to microscopic blood in the third glass.

(f) Pyuria is of course present in the pyogenic cases.

(g) Shreds of mucus embedding a few white and red blood cells are often noted in the nonpyogenic cases.

(h) Urinary obstruction or retention: Swinburne believes that inflammation of the veru induces spasmodic contraction of the compressor muscle, causing marked obstruction, and cites cases in which patients have difficulty in urinating, with residual urine as high as 16 ounces, in which the caliber of the urethra was normal and in which treatment of the inflamed verumontanum produced cure.

(i) Nocturnal enuresis occasionally occurs.

(j) There may also be mentioned an occasional symptom, dribbling of urine, a sensation of wetness in the urethra and a lack of the normal sensation at end of urination.

2. Genital symptoms:

(a) Diminution of sexual power ranging in degree from poor erection to absolute impotence. Michailoff believes the atonic form of impotence to be due entirely to a hyperemic stagnation in the region of the veru. Orbowski reports 310 cases of impotence in which the diagnosis of typical verumontanitis was made in 261. Of the 261 patients all but 16 were cured by treatment of the veru. Of the atypical cases more than half were not improved by treatment. He believes that in the 16 typical cases the lack of success was due to insufficient consideration of the secondary psychic manifestations. It must also be noted that a purely psychic impotence may develop, the patient presenting, also symptoms due to a demonstrable inflammation of the veru, prostatic urethra or trigon.

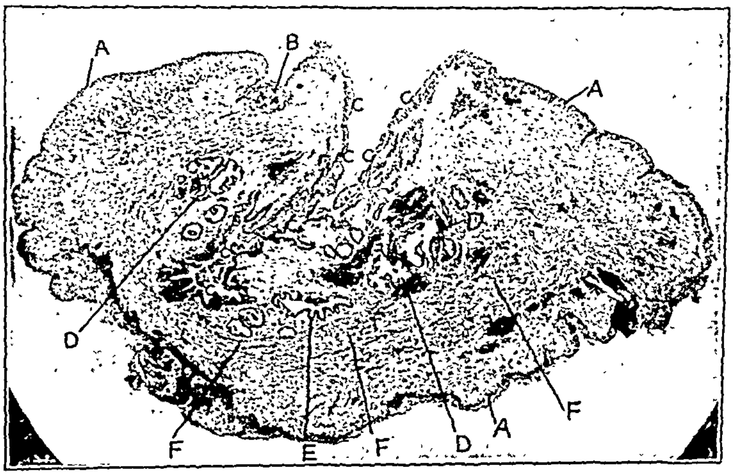

Fig. 2.—Section of normal verumontanum showing course and structure of sinus pocularis: *a*, mucous membrane; *b*, pit formation; *c*, sinus pocularis; *d*, central group of glands, some showing infoldings; *e*, duct; *f*, capsule; *g*, stroma. (After Rytina.)

(b) Premature, usually, occasionally delayed, ejaculation.

(c) Painful ejaculation: This symptom is common in the acute and subacute cases and usually is evidenced by a sharp stabbing pain, often referred to the perineum, sacral or coccygeal region. In some cases there will only be a burning sensation in the deep urethra, persisting for some time after ejaculation. This burning sensation is probably due to the inflamed mucosa surrounding the veru, while the sharp pain is undoubtedly due to the sudden stretching of the ejaculatory ducts, the lumens of which are diminished in caliber by the round-cell infiltration in the surrounding tissue.

(d) Priapism is, I believe, rare, although the acute cases sometimes show increased erections due to the irritation of the nerve ends in the posterior urethra.

(e) Nocturnal emissions: These are due to the infiltration of the collicle, which produces a mechanical atrophy of the muscles of the ejaculatory ducts.

3. Other symptoms:

(a) Referred pain is common in these cases. Some of the patients complain of a dull ache in the suprapubic region, but a great many suffer from actual pain, in the lumbar region particularly. This pain is sharp, often severe and remittent in type. This is often the only symptom the patient complains of and an inflamed veru is undoubtedly the cause of many, so-called, lumbar myalgias and neuralgias. The pain may also be referred to the testicle, coccyx or rectum.

(b) The suprapubic pain is common only in the acute cases, in which, with the inflammation of the veru there is hyperemia of the mucosa posterior to it and of the trigon. A persistent, mucoid, urethral discharge is sometimes present. Many of these patients are so neurotic that their symptoms must be regarded as due both to the actual lesion and to psychic disturbance.

DIAGNOSIS

I do not feel that the symptoms present a symptom complex. As I have stated, the cases usually present either urinary or sexual symptoms exclusively and not the admixture of both that we would expect: therefore we must, in any case showing any of the symptoms, regard the veru as a possible causative factor until eliminated by examination. In a routine genito-urinary examination, any undue sensitiveness in the prostatic urethra to the passage of bougies should arouse suspicion of verumontanitis.

In the urethroscopic diagnosis, examination of the verumontanum alone is not sufficient; the mucous membrane surrounding it must be examined carefully and if that is inflamed the trigone and bladder should be examined; the trigon and prostatic mucosa often being hyperemic, edematous and bullous in appearance. The straight tube of Young affords a better picture of the entire mucous membrane than the fenestrated curved tube, and facilitates treatment of the surrounding mucosa.

Diagnosis of inflammation of the veru should be made only after thorough examination of the prostate and vesicles and elimination of pathologic conditions of the kidney and bladder. The urethroscopic examination should not be made until after any irritation induced by the passage of bougies or instruments has subsided, as, otherwise, oozing of blood may obstruct clear vision. The passage of the urethroscope should not cause hemorrhage from a normal veru, and the presence of any bleeding, I feel, evidences pathologic change.

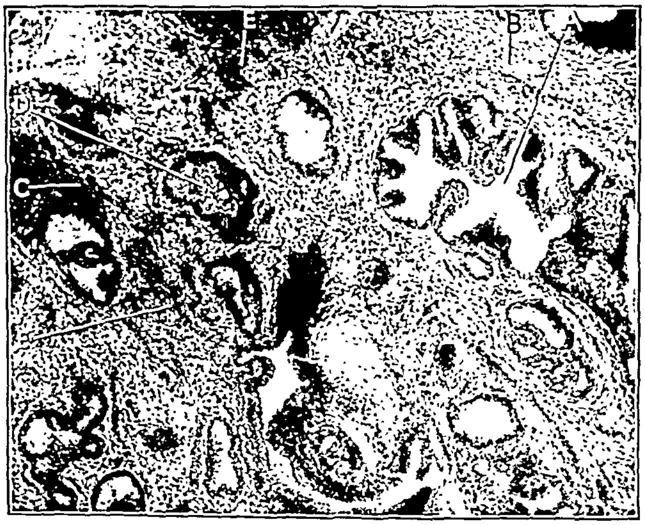

Fig. 3.—Section through an infected verumontanum. Infection is limited to left half; right half is normal: *a*, normal acinus showing infoldings, suggests prostatic hypertrophy; *b*, normal stroma; *c*, peri-acinous infiltration with round cells; *d*, normal acinus replaced by round-cell infiltration; *e*, infected stroma. (After Rytina.)

TREATMENT

In the pyogenic cases, emphasis must be laid on termination of infective processes in the prostate and vesicle, and treatment by injection of the sinus pocularis, while valuable, necessarily is only an adjunct in cases in which its infection resists the treatment directed to the prostate. In the acute nonpyogenic cases, treatment must be directed to the inflamed mucous membrane as well as the veru. I have seen several cases in which the mucosa of the prostatic urethra was so hyperemic and edematous that it was impossible at first clearly to outline the veru, but after one or two applications of a 5 to 10 per cent. silver nitrate solution to the mucous membrane, its condition returned to normal; the veru became well defined and the application of a strong silver nitrate solution to the veru itself cleared up the case. In the acute cases the local application of the weaker silver nitrate solution to all the inflamed mucosa of the prostatic urethra gives decided relief from the symptoms, which we must remember are not ascribable to the veru alone.

In the subacute cases I use 20 per cent. silver nitrate in those showing a soft, somewhat cystic veru, fused silver nitrate when the veru is larger and firmer, and confine the application to the veru alone. In these cases I neutralize the silver nitrate with sodium chlorid before removing the tube. In the chronic cases, I amputate the hypertrophied portion and apply fused silver nitrate. Hawkins states that if a little oil is left in the urethra after the application of the silver that the patient suffers much less. He uses eucalyptus 1 part, charcoal-filtered cylinder oil 7 parts.

The possibility of epididymitis developing during treatment must be considered even in nonvenereal cases. I have had cases develop several days after applying silver nitrate to the veru, and without other etiologic factor. I find that the treatment, particularly of the chronic cases, requires a great deal of tact. There is so much of the neurotic element in many of these men that the local condition must not alone be considered, and particularly if there is diminution of sexual power, the patient requires an optimistic prognosis and general tonic treatment. If this is neglected, the patient will not be cured even if the veru is restored to normal. Inflammation of the veru is also the basic factor in many neurotic and neurasthenic cases, as the neurologists are now recognizing. Gardner reports one patient who was committed to a state hospital for the insane because it was thought the patient imagined a pain in the neck of the bladder; the case clearing up on treatment of the veru.

As soon as the veru is normal in appearance, even if the patient still complains of symptoms, I stop all treatment, assure him that he will recover completely, advise him against worrying over his condition, make him take plenty of outdoor exercise and above all emphasize the fact of his eventual recovery.

REPORT OF CASES

Case 1.—A painter, married, aged 43. He denies venereal disease. During the last year he has had a feeling of irritation at the neck of the bladder, particularly when working. Urinary interval, two hours. He has a constant interval desire to urinate. Urination is not painful. There is no tenesmus or blood. The sexual act is normal. Genitals, urine, prostate, vas and vesicles are normal. A bougie causes pain in the prostatic urethra. The verumontanum is large, dark red and very tender. Silver nitrate stick applied three times gave entire relief from symptoms.

Case 2.—A bookkeeper, married, aged 25. He denies venereal disease. Three and one-half years ago he developed pain and irritation at the neck of the bladder. The condition had persisted and become gradually worse. He urinates every one to one and one-half hours. For three hours every day the patient feels normal; the remainder of the time he has a constant desire to urinate. He has a slight burning sensation in the deep urethra. The urine occasionally has shown white and red blood cells, but no bacteria. The verumontanum is twice normal size and very sensitive to pressure. The silver nitrate stick was applied. The first treatment gave relief from symptoms for eight days. In all, the patient was treated five times, improving after each treatment, but noticing some recurrence of symptoms after each treatment but the last. Four months after the last treatment the patient reported himself free from symptoms.

Case 3.—An accountant, married, aged 33. Patient had gonorrhea ten years ago and a symptomatic cure in three months; complains of pain in coccyx, particularly at night. He has loss of normal sensation during the sexual act. Urination is normal and painless, the urine negative. Genitals, prostate, etc., are normal. The verumontanum is inflamed, bleeding on touch, with a bleb on the left margin. Applied silver nitrate 20 per cent. once and 10 per cent. once. Four months later the patient reported himself free from coccygeal pains. Sexual powers and sensation are normal.

Case 4.—A porter, married, aged 24. The patient denies syphilis but had gonorhea five years ago, which persisted for several months. Urination interval is normal and painless. He has loss of sexual sensation. For some time he has had severe pain in the lumbar region, both sides. This pain is severe enough to make him seek treatment. The urine is negative. Examination revealed nothing but the severe pain produced by a bougie in the prostatic urethra. The verumontanum is intensely inflamed, filling the end of the urethroscope. Applied silver nitrate 20 per cent. Backache ceased the day following the treatment, but returned ten days later. Silver nitrate stick applied five times gave entire relief from symptoms.

Case 5.—A mason, unmarried, aged 20. Patient denies venereal disease. One year ago he developed great frequency of urination with severe burning along the course of the urethra with severe tenesmus and terminal hematuria. Cystoscopy at that time revealed a normal bladder. He made a gradual improvement, leaving the hospital in three weeks. The symptoms did not entirely leave and, becoming severe again, the patient was in the hospital for two weeks, gradually improved and was free from symptoms for eleven months. The present attack came on suddenly. He urinates every thirty minutes day and night. The third glass is red with blood; urine negative except for red blood cells. Urinary and sexual organs are normal. Cystoscopy shows bladder mucous membrane normal; the trigon slightly edematous, not inflamed. The kidneys were catheterized. Urine was negative. The verumontanum was larger than normal, soft, and did not bleed on pressure. The silver nitrate stick was applied. The patient immediately improved after the application of silver nitrate, leaving the hospital five days later. Silver nitrate was applied three times at ten-day intervals until the verumontanum was reduced to normal size. Two months later the patient reported himself perfectly well.

Case 6.—A mechanic, married, aged 34. The patient denies venereal disease. July, 1914, he had a urethral discharge, which has persisted. The discharge is slight and contains a few intracellular diplococci. The prostate on the left side is hard and distended. The prostatic secretion shows 75 white blood cells to the field. The patient came under observation Oct. 10, 1914. Urination interval is one hour; nocturia, 8. There is severe tenesmus. Sometimes the patient has passed a little blood with the urine.

Octo. 28, 1914: Patient urinates every fifteen minutes, the urine showing blood. There is constant burning and tenesmus. Cystoscopy negative, with the exception of congested trigon. The kidneys were catheterized, the urine was negative.

October 30: Endoscopy revealed a swollen, distended veru. The silver nitrate stick was applied. Six days after treatment the patient showed much improvement, with urination every two hours. Nocturia was 0 and patient had very little discomfort. He immediately began gaining weight and strength. Silver nitrate was applied twice subsequently and when seen December 19 the patient was feeling well. Urinary interval two and one-half hours; nocturia, 0 and 1; urine, negative.

April 10, 1915: Urethroscopy revealed a normal verumontanum and patient free from symptoms.

Case 7.—A clerk, unmarried, aged 23. The patient denies venereal disease. Has practiced masturbation sixteen years. The genitals are normal. The passage of sounds caused severe pain in the prostatic urethra. The verumontanum is swollen, edematous, bleeding easily. Silver nitrate 20 per cent. was applied three times until verumontanum became normal. The patient had no difficulty in breaking himself of the habit as the irritability which caused the desire left him with the improvement in his condition.

Case 8.—A farmer, unmarried, aged 18. The patient denies venereal disease. He has bladder distress, frequency of urination and pronounced tenesmus. The genitals are normal. Urine, all three glasses are cloudy with pus cells, the third containing a few red blood cells. The urine from the right kidney is negative; urine from the left kidney containing pus cells, but no bacteria. Cultures and inoculations were negative. The bladder showed chronic cystitis. The verumontanum is swollen, very edematous, bleeding on touch, practically filling the urethra. Treatment of the verumontanum gave the patient practically complete relief from his symptoms. Urination became painless and at regular intervals, the pus remaining, however, in the urine, until the pyelitis was cleared up by lavage.

507 Paulsen Building.

ABSTRACT OF DISCUSSION

Dr. Edgar G. Ballenger, Atlanta, Ga.: I have recently made it a little easier to apply these treatments by a slight modification of the endoscope. I had one made with rounded edges so that it could be introduced without an obturator. The observation may be made as the instrument passes in and the verumontanum is more easily found. Patients suffering from verumontanitis are very sensitive in that portion of their anatomy and greatly appreciate gentleness and speed in these treatments. By using this endoscope the passage of urine into the instrument causes considerable less annoyance than with the usual endoscope.

Dr. W. J. Pennock, Spokane, Wash.: I was glad to hear Dr. Ballenger's suggestion with regard to the instrument. I am not quite satisfied with our instruments at the present time, and I am very glad that Dr. Ballenger has found something better. There is no question about the necessity of giving these patients as little pain as possible, as the treatment must necessarily be administered more than once and the patient is not usually very glad to come back to you. I go into the bladder with the endoscope and then draw the endoscope forward, feeling that it is quite important to make a careful study of the mucous membrane of the prostatic urethra.

Iron Bacteria.—It has been known for many years, says E. C. Harder, (*Science*, Sept. 3, 1915, p. 310) that some of the higher bacteria are concerned in the precipitation of ferric hydroxid from iron-bearing waters. Thus, in city water pipes the frequent turbidity of water containing a small percentage of iron and the occasional filling of the pipes with ferric hydroxid has been attributed to *Crenothrix polyspora*. Other forms have been found abundantly present in surface iron-bearing waters, and it has been asserted that such bacteria play an important part in the formation of numerous small deposits of bog iron ore. Harder thinks it possible that they may also be in part responsible for extensive beds of sedimentary iron ore. In a field study of the subject, Harder has found iron bacteria present in almost all iron-bearing waters, both surface and underground, including the workings of mines to a depth of several hundred feet. The last-mentioned fact, Harder thinks, suggests the possibility that certain underground deposits of iron ore have been formed by these bacteria.

THE VALUE OF THE COMBINATION METHOD IN THE TREATMENT OF CERVICAL CARCINOMA

S. M. D. CLARK, M.D.
Professor of Gynecology and Clinical Obstetrics, Tulane University of Louisiana, School of Medicine
NEW ORLEANS

Although it has been known for centuries that cancer is peculiarly susceptible to heat, its application was not established on an intelligent basis until Percy, in 1912, experimentally proved that cancer cells would be destroyed when exposed to a temperature of 113 F. for twenty minutes, and, further, that the normal tissue would live in a temperature as high as 131.9 F.

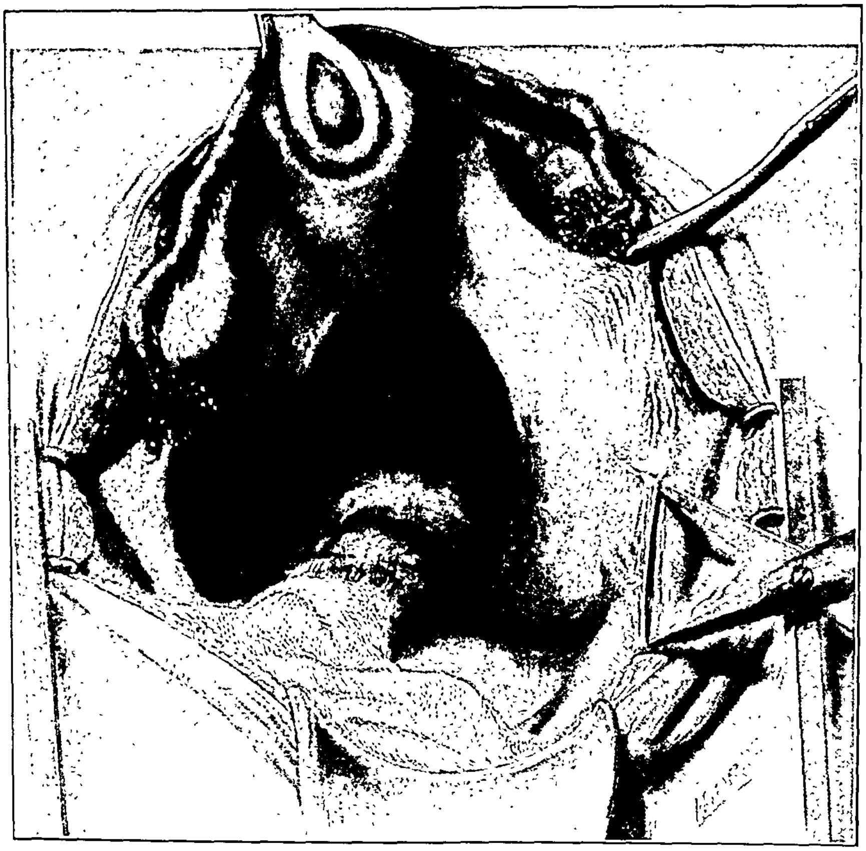

Fig. 1.—The right infundibulopelvic ligament put on stretch, bringing ovarian vessels into view. Mayo scissors in peritoneal nick at bifurcation of common iliac.

With this as a fundamental principle, he worked out a scheme by which heat could be applied to cervical carcinoma on a far more elaborate scale than had ever heretofore been possible. Up to this time we had been trying to realize the same brilliant results accomplished by Byrne of Brooklyn, but he left no definite technical plan to follow. Each worker groped along independent lines. There was no definite knowledge of the physical effect of heat on cancer cells, and consequently individual efforts ended in gross disappointment.

The perfection of this elaborate heat method marks a brilliant epoch in the cancer problem. Though possessing many admirable qualities, it does not seem to me, when viewed in the light of a cure, that it is a method to be *singly used.* It should be classed as a *valuable adjunct,* and its chief virtues are to be witnessed when combined with other equally valuable but operative methods.

In my first cases the hot irons were used only in advanced inoperable cases. Certain of these women showed such noted improvement, both locally and constitutionally, that it was disappointing to realize that their condition was only temporary. When the slough would detach, the bleeding stop, and the toxemia diminish, these desiccated, cadaverous individuals would be transformed into a state of apparent health. As a result of the stimulation through these initial encouraging results, the use of the method was broadened and was found to be admirably adapted to transforming cases less advanced, though still inoperable, into safely operable risks.

Two of our first advanced cases had severe hemorrhages following the detachment of the slough. In one instance, the hemorrhage proved fatal, and in the other was controlled by packing.

With the hand in the abdomen to control the degree of heat, both internal iliacs and one ovarian were ligated for the special purpose of coping with this serious complication. This step splendidly accomplished the desired end, since we have had no secondary hemorrhage within six months after its application. Though this preliminary ligation was done primarily to control secondary hemorrhage, its evolution has taught me that it possesses other commendable points.

In this extensive ligation, twenty-five arterial trunks are shut off, the uterus receives only a limited supply of blood through the one ovarian, and as shown by Dawbarn, the resulting starvation produces a marked retarding influence over the growth. Second, while the iliacs are being tied, the angle of the bifurcation of the common iliac can be explored for lymphatics, which, when removed, are a valuable prognostic guide as to the advisability and wisdom of further subsequent radical operation. Third, as a preliminary hemostatic for primary or later Wertheim removal, it notably controls operative hemorrhage. Last, as a result of these ligations, the slough seemingly detaches sooner, and the vault of the vagina clears more rapidly.

For purposes of discussion, cervical carcinoma may be conveniently divided into the following groups:

Group 1: Incipient cases. Ulceration strictly limited to cervix. Free mobility. No infiltration. Occasional unaccountable show. Menses slightly prolonged. Constitutionally unimpaired.

Group 2: Cervix well infiltrated with carcinoma. Growth just beginning to spread to vaginal walls. Uterus still movable, though there is a definite thickening in its lower and middle segment. No appreciable lateral infiltration. No pain in sides. Having copious bleeding. Secondary anemia and constitutionally below par. The type in which the radical operation is reluctantly considered from the standpoints both of primary mortality and of permanent cure.

Group 3: Either a crater or large cauliflower mass in vault of vagina. Notable lateral infiltration as well as involvement of vaginal wall at least an inch from cervix. Decided impairment of mobility. Pain in sides. Marked cachexia and anemia. Constitutionally and locally surgically impossible from radical standpoint.

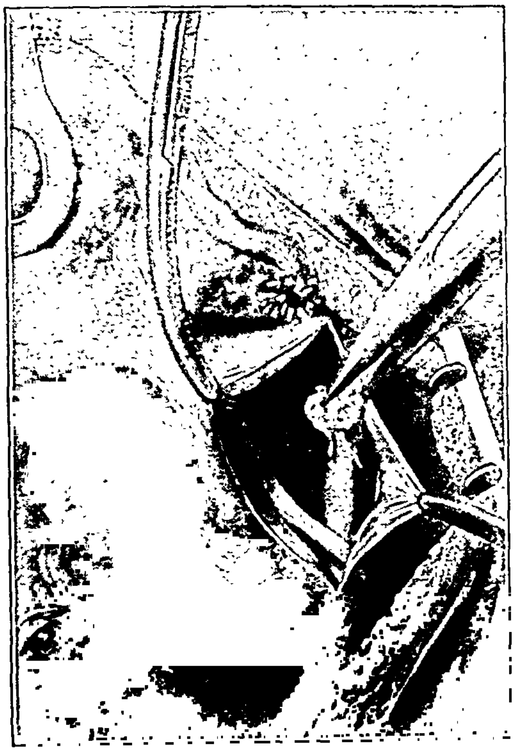

Fig. 2.—Bifurcation of common iliac with ureter attached to inner peritoneal flap and lymph gland being removed.

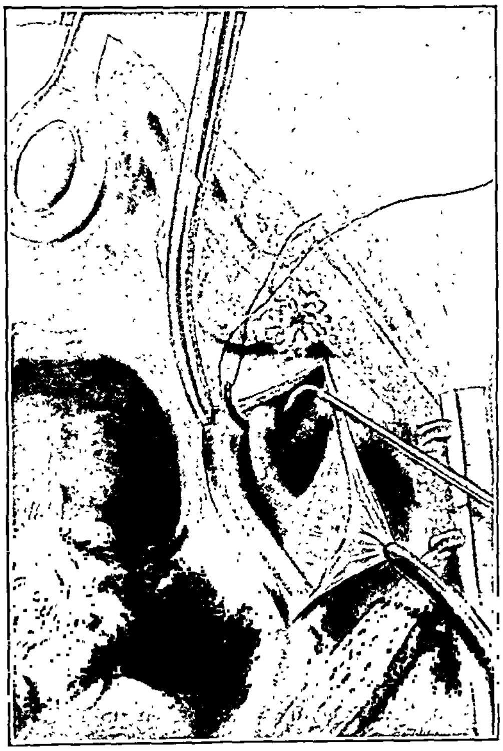

Fig. 3.—Ligation of internal iliac. Not necessary to open sheath. By lifting exposed vessel with forceps, needle can be passed without danger of injury to underlying vein.

Group 4: Hopelessly advanced. Conglomerate metastases of rectum, bladder and vagina. Inguinal lymphatics involved. Constant losing with foul odor. Constitutionally wrecked. Opium habitués.

FIRST GROUP

Cases falling in the first group are treated by combining at the one sitting the application of heat with the Wertheim removal. The abdomen is opened, thoroughly packed off, and as a prophylactic hemostatic measure, both internal iliacs are ligated, which excellently serves in reducing bleeding so frequently associated with the radical work.

The hot iron is now applied for twenty minutes, the hand being used within the abdomen as a guide to the position and degree of heat of the cautery. Heat is used here to destroy cancer cells, in the belief that the risk of grafting cancer through manipulation is thereby diminished; further, it aids in sterilizing the vaginal vault. Iodin is liberally applied to the vaginal canal, and the radical work immediately follows.

Where there exist no physical contraindications, the combination of these two valuable measures gives the best chance for permanent cure. I have seen fairly early cases in good physical condition treated only by the cautery, in which in six or eight months there would be a return of the disease at the site of the former burning. To follow the heat with radical removal unquestionably gives a better end-result. The heat adds not more than twenty-five minutes to the sitting, and with a good surgical risk, it is not too taxing to perform the Wertheim removal immediately afterward.

In extremely obese women of small stature, it is a physical impossibility to operate radically; furthermore, if it were possible, the primary mortality would be so high as to render the procedure unwise. Here the liberal application of heat offers the best and only chance, as these patients are unfit for the extensive operating, and yet can well withstand the abdominal incision for the introduction of the guiding hand.

SECOND GROUP

In the second group, the Percy method occupies a unique position in that it *converts* the constitutionally unfit into good surgical risks, and too, causes marked shrinkage in the local area. By employing it in combination with ligation of both internal iliacs and one ovarian at the first sitting, with a three and a half weeks' interval, these surgically doubtful risks are literally transformed into safely operable cases.

This procedure produces little or no shock; in fact, it is striking to see how readily these poor risks tolerate this first sitting. The plan adopted is to cook and ligate, and then let the patient remain in bed about ten days, at which time the slough detaches. The hemorrhage and toxemia having been controlled, the patient is permitted to return home and ordered daily douches and forced feeding.

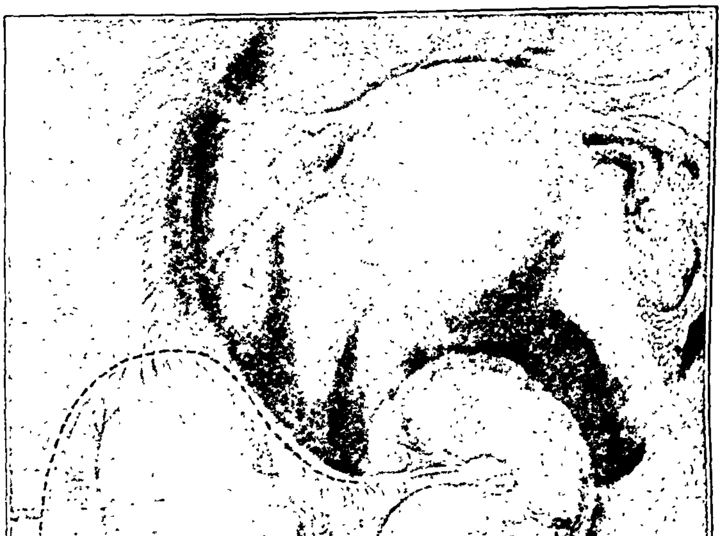

Fig. 4.—Line of dashes shows line of incision, should it be found necessary to reflect sigmoid to reach bifurcation of common iliac. Not as yet found necessary.

From three to five weeks after this first sitting, the picture has changed, the hemoglobin has risen from 15 to 25 per cent., the vessels are full, the entire economy has steadily improved and from being a questionable surgical undertaking, the case is lifted both locally and constitutionally into a frankly operable state.

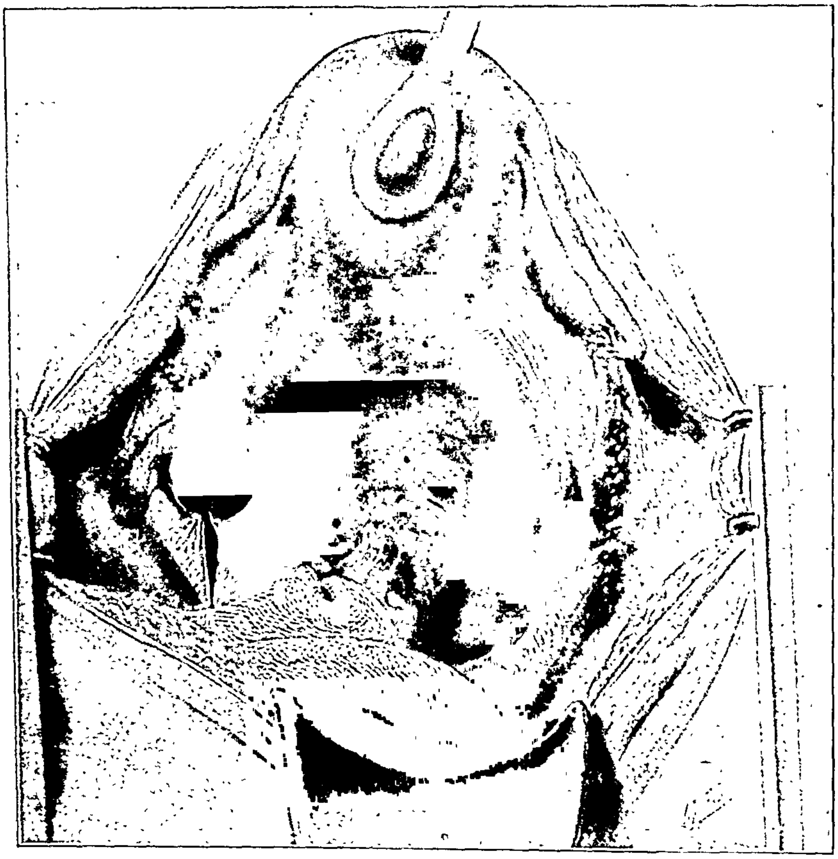

Fig. 5.—Peritoneal rents closed with continuous whip-stretch, full curved, round needle. Right ovarian artery tied.

Prior to my experience with the heat method, I can vividly recall certain patients who were clearly operable from a local standpoint, but who were notably depleted from hemorrhage, and after the major extirpation, simply did not have sufficient reserve force to get well. They would gradually lose ground and die on about the tenth day from no apparent cause, except exhaustion.

By the use of this two-stage plan, such cases can be radically improved, and I feel that it can be positively asserted that it is a method which *increases* the *operability* of cervical cancer, as well as *reduces* its *primary mortality.*

THIRD GROUP

The third group of cases has heretofore been considered hopeless. The patients would as a rule be superficially singed, and sent home to die. Since employing the elaborate heat plan as a routine in combination with internal iliac and one ovarian ligation, I feel that, though permanent relief is not as a rule to be expected, still much genuine comfort and *some* cures can be given this group.

Pathologists have taught us that it is not possible to tell from the macroscopic appearance of a cervical cancer just to what extent it has metastasized. The pathologist of the Cancer Hospital at London held routine necropsies in 100 unoperated cases with death of cancer, and found that in 46 per cent. of these cases, the lymphatics were not involved beyond the pelvis, and from the side of lymphatic invasion, these cases were curable from an operative standpoint. Even though we accept these flattering statistics with some reserve, it gives a reasonable basis for a cure in some advanced cases, and further explains some of the sporadic cures with the old zinc chlorid treatment.

The same combination plan is adopted in this group. While in the abdomen, the infiltration is specially studied with a view to possible removal, and also while ligating the iliacs the lymphatics are removed to be later sectioned for metastasis. If the infiltration is too extensive, or if the iliac glands are metastasized, the case is abandoned as a hope for radical cure. On the other hand, if the glands are negative and the large mass is believed to be partly due to a chronic infection, the woman is allowed to transform and subsequently is given the benefit of a radical operation.

In my list I have had two cases which, when first seen, were obviously inoperable, but after the use of the combination method, they changed so completely that the Wertheim operation was performed.

Much to my surprise, even after very careful search, no cancer cells could be found in either of these specimens. Though carefully feeling my way in this group, and not having as yet formulated a positive conclusion, my results thus far have been sufficiently encouraging to warrant further study. Where the condition is so aggravated as to prohibit radical surgery, the ligation and heat give great temporary relief.

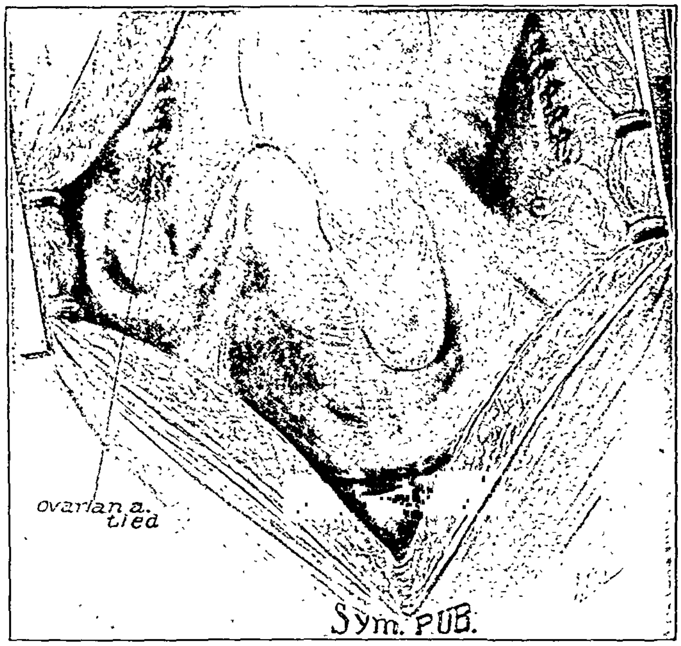

Fig. 6.—Ovarian artery tied and peritoneum closed over ligated internal iliacs. Hand grasping uterus with fingers extending down around basal structures to guide Percy cautery and control heat. Cautery schematically shown embedded in lower half of uterus—inserted by vagina.

In two of these advanced cases in which such noted improvement followed the combined method, the uterus having greatly increased in mobility, as well as a general shrinkage of the tumor mass having occurred, I thought it possible to perform the Wertheim operation. But when this was attempted, it was found as a result of the heat destruction that the upper two thirds of the uterus, when liberated, parted from the mass in the vaginal vault, thus rendering further radical procedure unwise, but still giving an opportunity to apply the heat to this remaining area through the abdominal route. Where the mobility of the uterus is solely employed as a guide to operability in these advanced cases, one will necessarily encounter this disappointing experience in a certain number of cases.

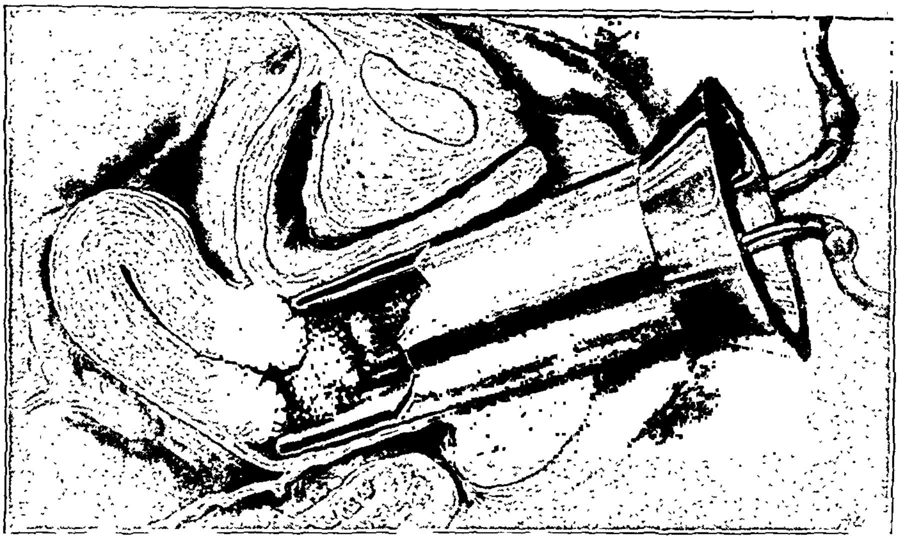

Fig. 7.—Gelpi's water-cooled speculum introduced into the vagina, bringing into view an external cervical carcinoma.

It is in the third group that the vesicovaginal fistulas are encountered. Five such complications have resulted in my cases. After the destruction of the initial mass and entire cervix, there remains a huge crater with suspicious nodular areas demanding further cauterization. Since the upper boundary of this cavity is the bladder itself, it is almost impossible to avoid damaging its wall in subsequent heat application. In order to overcome this feature, we are devising an accessory water-cooled speculum like a flat spoon to fit underneath this exposed vulnerable area.

Unfortunately, the third group is a very large one. In it are found some of our most interesting problems, and though further study is necessary before positive conclusion can be deducted, still it presents a field in which much can be done.

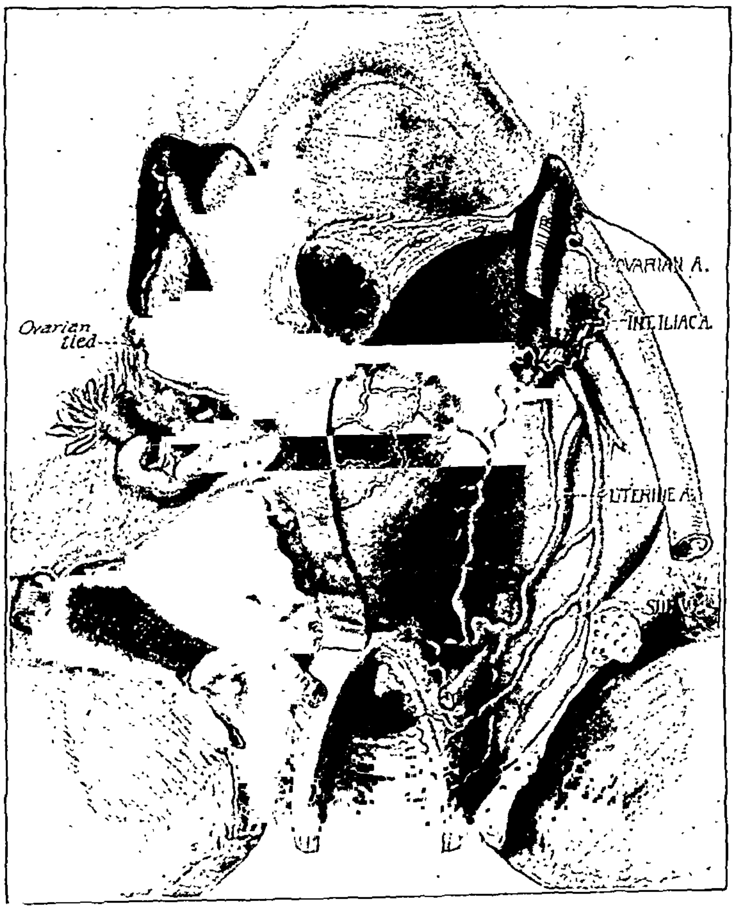

Fig. 8.—Semischematic figure showing uterine arterial collateral circulation via ovarian. Left internal iliac ligated, and right ovarian tied through peritoneum.

Permanent cures are not, as a rule, to be expected; but in view of my experience with this combination method, I feel that these patients should be more painstakingly studied and not, after the most superficial consideration, as is the usual custom, be relegated to the life of a morphin habitué. Thus far, through the use of this method, it can be stated that some surprisingly satisfactory results have been realized. In the majority, not only has there been given marked comfort, but a definite extension of life; and further, in a certain small number, there has apparently been given a cure.

FOURTH GROUP

The fourth group is the absolutely hopeless class. From early experience, I have learned that more harm than good follows any attempt toward local interference. It is to be hoped that, as a result of improved medical education, combined with the educational work now being so splendidly conducted by the Cancer Commission, this group will greatly diminish.

Last December, I presented a preliminary report of this work to the Southern Surgical and Gynecological Association, at which time I discussed the heat technic. Since this time, the only radical change in method has been the addition of extensive arterial ligation. This communication was based on the observation of twenty-five cases; the number has now increased to forty-two. While it would be most desirable to submit at this time a detail analysis of each case with end-results, this would not be feasible, since the work is still in its infancy. However, since the use of this combination method, it can be stated that there has not been a single primary death following the ligation and heating, or from the Wertheim removal.

Five years will have to elapse before end-results can be reasonably computed, but my experience with this plan of attack has so completely surpassed former methods of treatment, that I feel fully justified in presenting at this time the subject for discussion.

SUMMARY

1. The heat method alone has doubtful curative properties, and should be viewed in the light of a valuable adjunct in the treatment of cervical car-

cinoma. However, in extremely obese women, it offers the best and only chance for a permanent cure.

2. Heat should be used as a routine in all types of cervical carcinoma, except in hopelessly advanced cases (Group 4).

3. The ligation of both internal iliacs and one ovarian possesses definite merit, and when combined with heat, furnishes the best means of converting the borderline cases into frankly operable ones.

4. It cannot be too strongly emphasized that the combined application of heat and ligation of vessels, on the one hand, and total extirpation, on the other, in all except clearly operable cases, should be done as a two-stage operation.

5. In the combination of heat with starvation, we have a valuable means of markedly increasing the operability and of decreasing the primary mortality of radical extirpation.

6. Heat combined with extensive arterial ligation, followed by radical hysterectomy, offers the greatest possibilities for permanent cure.

GUINEA-WORM DISEASE

GEORGE G. DAVIS, M.D.
AND
J. J. HILTON, M.D.
Surgeons, Chicago Medical Unit, Twenty-Third, General Hospital,
British Expeditionary Force
ETAPLES, FRANCE

The occurrence of a parasitic disease, which is spread by drinking water, and found in an army force, in a country generally free from these parasites, seems of sufficient interest and importance to warrant a rather extended study of the case. Dracontiasis or guinea-worm disease occurs frequently in Africa and East India. It is rare in the United States, only a few cases having been reported, and these are mostly imported, although Van Harlingen's case occurred in a man who had always lived in Philadelphia.

In man, the female worm develops in the subcutaneous and intermuscular connective tisue and produces vesicles and abscesses.

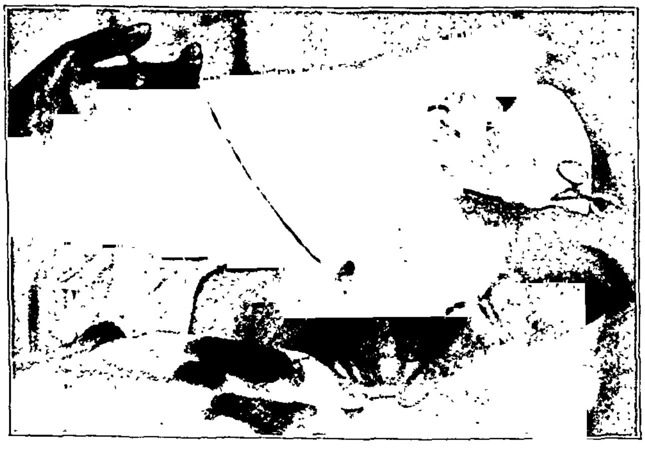

Fig. 1.—Guinea-worm being gently drawn from the subcutaneous tissue of the left foot.

The parasites are generally found in the lower extremities. Of 181 cases, 124 occurred in the feet, thirty-three in the leg, and eleven in the thigh. The worm is usually solitary, although six or more have been present in the same patient. The worm is cylindrical in form, 2 mm. in diameter, and from 50 to 80 cm. in length.

The parasite gains entrance through the stomach and not through the skin, as is usually supposed. The male and female are ingested. The former dies and is discharged, but the latter after impregnation penetrates the intestines and attains full growth in the subcutaneous tissue, where it remains for a considerable time and may be palpated beneath the skin, feeling like a nest of worms.

The worm, in its endeavor to rid itself of its large number of living embryos, burrows head first downward, until it reaches the foot or ankle, where the head, penetrating the skin, causes a vesicle in the epidermis, which ruptures and results in an ulcer, through which the head projects. After the distended uterus ruptures, and the embryos are cast off in a whitish fluid, the worm generally leaves the host. These embryos contaminate the water, and develop in the cyclops, a small crustacean, and it is likely that man is infected by drinking the water containing these developed larvae.

The history of our case is as follows:

Lance-Corporal D. L., Second Cameron Highlanders, Company D, has seen service seven and a half years, five of which he spent in India. Since October, 1914, he has been at the front in France. Before he entered the service, he was a blacksmith in Glasgow, Scotland.

Patient states that while swimming in the rear of the trenches, six weeks before, he was injured by a barbed wire, receiving slight flesh wounds of the left foot, below the internal malleolus, and of the right foot on the dorsal surface. He believed the wounds insignificant at the time, and painted both wounds with tincture of iodin, applied no dressings, and continued on duty. In two weeks the wounds were almost completely healed, but in the course of another week, the left foot became tender, swollen, and finally suppurated. The inguinal glands on that side also became swollen and painful. He does not know whether he had any fever or not. At this time he reported to his regimental surgeon, who opened the wound and applied wet dressings. The wound partially healed, after which he went to the trenches for seven days, and again his foot became swollen and tender. This time he was sent to the clearing hospital, where it was again opened, and, following which he arrived at this hospital.

The patient states that coincidently with the primary injury he noticed a white, raised area on the flexor surface of the left forearm. A member of his regiment who had served with him in India broke the vesicle and removed a worm, by carefully wrapping it around a lead pencil. It was 2 feet in length. The wound closed and is now the site of a small pigmented scar. In regard to the patient's previous history, he stated that he did not remember having had any of the diseases of childhood, but had suffered from a severe attack of tonsillitis in 1911. He denies any venereal history. During his five years' service in India, he enjoyed good health, except for an occasional chill, followed by sweats and rise in temperature. These attacks persisted in spite of prophylactic doses of quinin taken twice weekly. All the water he drank while in India had been previously chlorinated. His family history is negative.

Examination of the wounds on the median aspect of the left foot, below the internal malleolus, showed a large, infected, irregularly shaped ulcer, about the size of a silver 25-cent piece. Its ragged necrotic edges were undermined for a variable distance of from 2 to 4 cm., and several sinuses extended upward and exuded pus, and sanguinopurulent material. The base of the ulcer consisted of unhealthy and uneven granulations. The region about the wound and half way up the leg was quite tender. The inguinal glands on this side were enlarged and painful.

On the lateral aspect of the dorsal surface of the right foot was a small abrasion surrounded by an inflamed zone, which was also tender. The inguinal glands on this side were enlarged, but not very tender. Aside from local findings, the patient had a marked chronic pharyngitis, and acne vulgaris of chest and back. His chest and lungs were negative. Abdomen was tympanitic and somewhat distended, but no areas of tenderness were present. The spleen was not palpable. Liver, which was palpable, came just below costal margin. Reflexes were normal, and genitalia showed scars. Blood examination showed: hemoglobin, 85 per [illegible] red blood corpuscles, 5,000,000; white blood corpuscles, [illegible]00; differential count: polymorphonuclears, 54 per cent.; lymphocytes, 36 per cent.; eosinophils, 10 per cent. The urinalysis revealed the specific gravity of the urine as 1.024; slightly acid, no bile, albumin or sugar.

Under ether anesthesia, the feet having been rendered bloodless by a Martin constrictor, both lesions were opened. In the left foot about 3 c.c. of pus were found. Culture from this was made and later showed *Staphylococcus pyogenes albus* and *Streptococcus pyogenes*. When the necrotic subcutaneous tissue was being dissected, a long tortuous, cylindrical organism was noted, which could by gentle traction be partially dislodged from its bed. By too great or sudden traction the organism would break, but another coil could be found in the tissue, and again traction applied. One organism was removed in toto. It was impossible to judge the number of worms in this foot, as it was difficult to decide whether several parts of one or of more than one worm were removed. There were certainly at least two, as one entire worm was removed.

The conditions in the right foot were quite similar, but no worm was removed in toto. The report from the pathologist, Dr. R. L. Thompson, was as follows: "Specimen consists of several white stringlike parasites, varying in length, and tough in consistency. One of these seems to be a complete worm. The others are fragments of other similar worms. The complete worm measured 32 cm. in length by 3 mm. in circumference. The body is round, semitransparent, and filled with numerous small, milky, white bodies (embryos). The end of the worm tapers to a sharp point, which is slightly curved at the extreme tip. Diagnosis (by Sir William Leishman) *Dracunculus medinensis*, or guinea-worm."

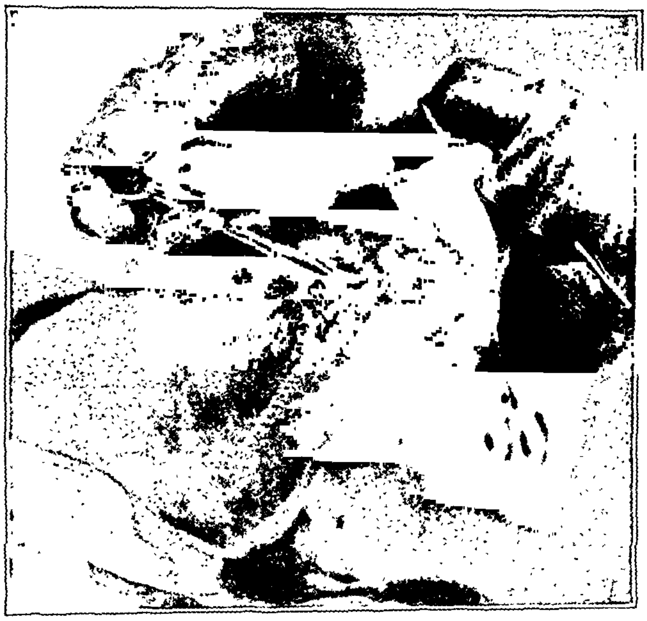

Fig. 2.—Necrotic tissue, and site of lesion on lateral aspect of right foot.

As this patient has recently returned from India, and as no other cases of guinea-worm disease have occurred in this vicinity, it is reasonable to suppose that this patient was infected in India, and that he has imported the disease.

The statement of the patient that the original lesion dated from an injury by barbed wire, and the occurrence of the worm at the site of the injury are worthy of note. Whether the worm was really the etiologic factor in producing the lesion, or whether it was attracted to the site of injury, is of course a question.

It seems that the removal of this worm may be effected better by prolonged traction, that is, wrapping the worm around an instrument and not allowing it to retract, than by operative procedure — endeavoring to excise the worm — as it may be divided and portions with embryos may remain and cause trouble later. The secondary pus infection should, of course, be treated by the usual surgical procedure.

A CASE OF CONGENITAL PERINEAL TESTICLE

G. M. LOEWE, M.D.
Urologist to the North Chicago Hospital
CHICAGO

The infrequency of congenital perineal testicle is best shown by the report of Grégan (Montpellier, 1913), who collected records of eighty-three cases up to the year 1913, but did not state what proportion of these were congenital, since this type is by far the more uncommon.

The literature dating from this time contains reports of three cases of perineal testicle, two of which were of the traumatic variety (Bevan, A. D.: The Surgical Treatment of Undescended Testicle, The Journal, Sept. 19, 1903, p. 718. Mulligan, R. A.: *Proc. Roy. Soc. Med.*, London, 1912-1913, vi. Simpson, J. S.: *Med. and Surg. Rep., Episc. Hosp.*, Philadelphia, 1914, ii).

I wish to report another case of the rarer type: the congenital form of perineal testicle.

The patient, a boy of 12, had complained for the past six months of pain in the perineal region when in the sitting posture, especially when suddenly arising and on running. The pain was described as dull and aching and recently increasing in intensity. His mother stated that when the boy remained seated he would constantly change his position, shifting from one gluteal region to the other. Examination showed that the patient was somewhat undersized but mentally normal. The right side of the scrotum was atrophied, and the left testicle was found normal in all respects. The perineal region showed an oval body which measured about 2.5 by 1.5 cm., located 5 cm. anterior to the anus and 2 cm. to the right of the median raphé. The mass gave a testicular sensation on pressure, and could be easily manipulated from the area just anterior to the anus to the region of the right external abdominal ring, but could not be placed into the scrotum. The mother then volunteered the information that the absence of the right testicle had been noted about two weeks after the child's birth, but that no further attention had been given to it.

At operation (Beck) an incision about 5 cm. long was made over the right external abdominal ring. The cord was seen emerging from the ring and extending down to the ectopic perineal testis. Attached to the lower pole of the testicle was a strong fibrous band, the gubernaculum testis, which was attached 2 cm. anterior to the anus and about the same distance from the median raphé. The gubernaculum was excised from the testis just below its attachment, and the somewhat underdeveloped te[illegible] placed [illegible] scrotum in the usual manner. T[illegible]ery wa[illegible] the patient leaving the hospital o[illegible]th day [illegible]

Four weeks later, the testicl[illegible] in n[illegible] and seemed normal in all re[illegible]

SARCOMATOUS PROLIFERATION (SARCOMA OF RIB)

IN A TRAUMATIC TUMOR SIXTEEN YEARS AFTER ITS FIRST APPEARANCE

JOHN H. OUTLAND, M.D.
Surgeon to the Swedish and Bethany Hospitals
AND
LOGAN CLENDENING, M.D.
KANSAS CITY, MO.

The question as to how long cells which are malignant or potentially malignant can remain in the body without manifesting any tendency to grow, proliferate or metastasize is one of great interest which may throw considerable light on the entire subject of malignant tumors.

Paterson[1] describes a case of gastric cancer in which he operated two years after the onset of symptoms. He found an inoperable carcinoma at the pylorus and did a gastro-enterostomy. The patient continued in good health for six years, without any symptom of extension of the growth or metastasis. Here we have a known cancer which was present for eight years in a spot richly supplied with lymphatics, with no tendency to manifest the ordinary nature of a cancer.

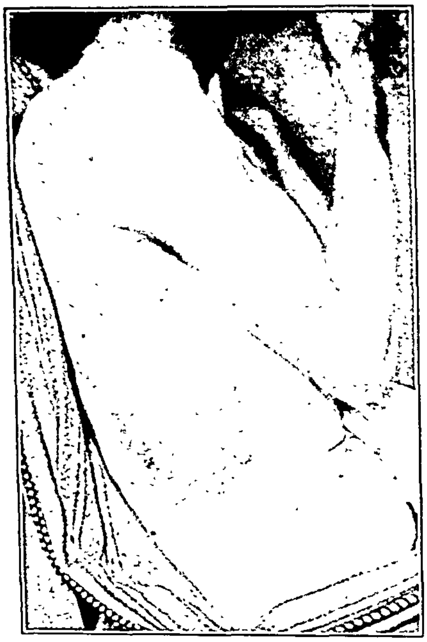

Fig. 1.—Tumor, painted with iodin.

Hertzler[2] has told us of a case of cancer of the breast in which he operated fifteen years ago. The patient has been under observation repeatedly in the interval. At the fourteen-year period she had had no metastasis or extension when she reported for examination. Nine months later she had a small recurrence in the upper end of the scar.

The following case, which deals with a sarcoma, is in line with these cases:

Summary.—Man, aged 36, received a trauma which resulted in the appearance of two small tumors over the region of the ninth rib. These tumors had been present sixteen years, when a sarcoma of the rib beneath them resulted. On removal, these tumors were seen to be sarcomas of the same structure as the sarcoma of the rib.

History.—The man, a farmer, was first seen by us Oct. 3, 1913. Family history was not significant. Personal history was negative for syphilis, rheumatism, tonsillitis and typhoid. At the age of 14, the patient was kicked in the right knee by a horse, sustained a fracture, and has had an ankylosed knee ever since. At the age of 19 he fell across a log, lighting on the right side of his chest in the axillary line. The injury was slight, but within a week or so two small lumps appeared under the skin at the level of the ninth and tenth ribs in the midaxillary line on the right side. They have always been painless, and have never grown sufficiently to notice; in fact, so far as the patient has noticed, they have always remained exactly stationary in size. They have been movable, the size of plums, and soft in consistency. His physicians, including ourselves, have always told him they were lipomas.

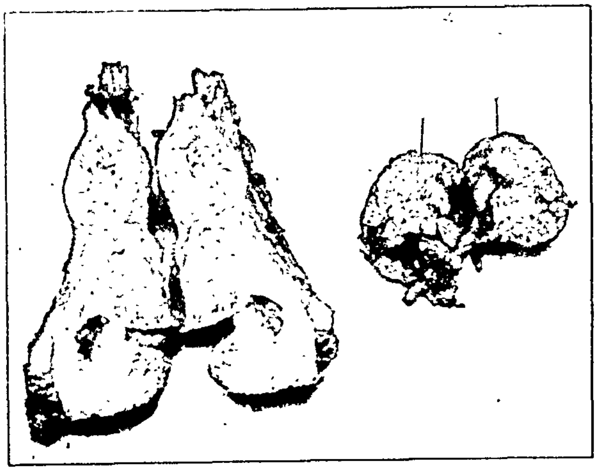

Fig. 2.—Same as Figure 3, with the tumors split open.

Nine months ago, without previous injury, he noticed that a hard lump had appeared over the ninth rib on the right side just under these old tumors. It was much larder, somewhat painful and not movable under the skin. It grew slowly at first, but has grown very rapidly during the last three months.

Examination.—Temperature, 98.5; pulse, 86; blood pressure, 120; leukocytes, 6,000; heart and lungs, no abnormalities. There is a hard mass, about 4 by 5 inches, over lower ribs on the right side. It is dense and adherent to the ribs. Two smaller masses in the same locality, movable under the skin, feel like lipomas.

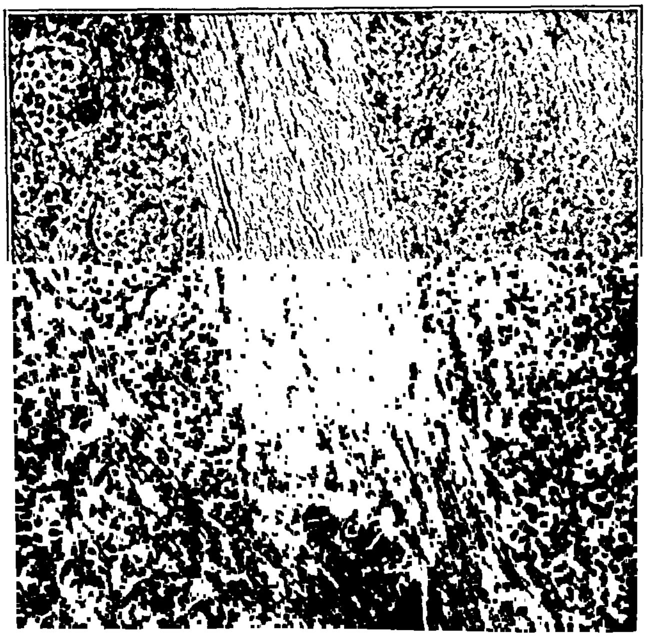

Fig. 3.—Photomicrograph of tumor on rib.

Operation.—Oct. 3, 1913, under gas-ether anesthesia, by the ordinary method, no attempt being made to use the negative pressure cabinet or intratracheal insufflation, a mass was revealed, comprising parts of the ninth and tenth ribs, which was removed by resecting these ribs without opening the pleura. A small plaque of growth on the pleura was revealed just under the site of the growth on the ribs, and necessitated the opening of the pleura for its removal.

---

[1] Paterson, in Murphy's Clinics, iii, No. 1.

[2] Hertzler, A. E.: Personal communication to the authors.

The two small tumors previously mentioned were seen to be purplish encapsulated masses in the muscle and subcutaneous tissue, and were easily removed.

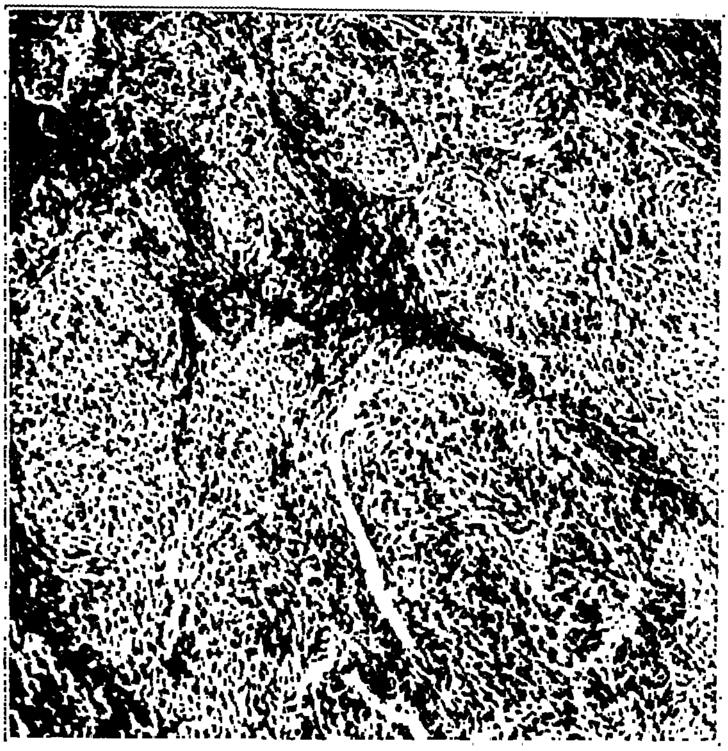

Fig. 4.—Photomicrograph of one of the small original tumors.

Pathologic Examination.—The material consisted of: (*a*) parts of two ribs united by a hard, dense, white fibrous growth, the size of a man's hand, and (*b*) two small lumps of tissue, which were soft and were encapsulated everywhere by a membrane as thick as the dura mater. On section, both of these showed the structure of a small round-cell sarcoma. The sarcoma from the ribs was interlaced with fibrous strands, while the small tumors were almost free from connective tissue framework.

Certain points in connection with this case may perhaps be emphasized. First, the identical structure of all these tumors: the original tumors and the new tumor on the ribs are all the same sort of sarcoma. Second, the complete encapsulation of original tumors. Third, the fact that they had been present for sixteen years without pain or growth.

The question arises whether they were sarcomas from the start, that is, whether they were the original focus of sarcoma, or whether they simply suffered in the general sarcomatous degeneration in the region. Whether, in short, the sarcoma was primary in the ribs or in these small tumors. Whoever defends the hypothesis that it was primary in the ribs will have to take into consideration the necessity for an explanation of the fact that a sarcoma developed at the exact site of a trauma received sixteen years previously.

Lund[3] reviews the surgery of sarcoma of the chest wall. The entire number of cases collected by him was twenty, to which he added one personal case. The case here reported is therefore of interest on account of its rarity as well as its pathologic significance.

Rialto Building.

FISTULA OF THE ESOPHAGUS AND BRONCHUS

REPORT OF A CASE, WITH ROENTGENOLOGIC FINDINGS

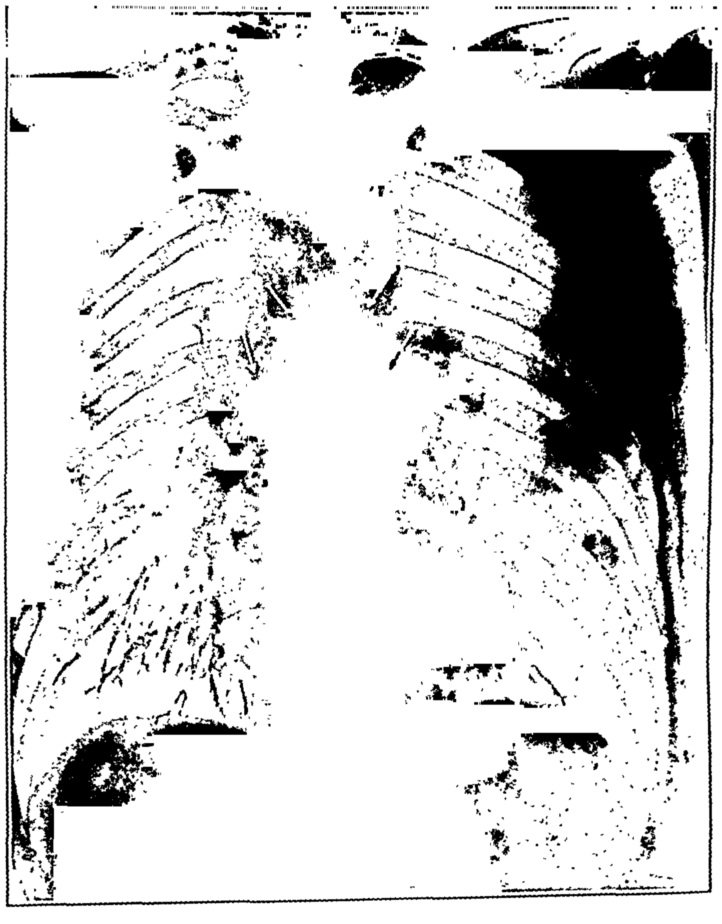
Raymond Cole Beeler, M.D., Indianapolis

On the afternoon of May 7, 1915, I was called to the Indianapolis City Hospital to make a Roentgen examination of the esophagus. The patient had been admitted to the hospital that afternoon and had alarmed the intern, so he called a member of the attending staff.

History.—Mr. H. C. B., aged 58, white, a native of Ireland, married, in the real estate business, with negative family history, had had syphilis forty years ago and myocarditis one year ago; he denied gonorrhea, and there was no history of swallowing escharotics. The present illness began six months ago with difficulty in swallowing. The patient was unable to swallow solids or liquids. He then got better and worse. This continued until one week ago, when he had a hemorrhage of bright red blood which he thought was from the stomach. Up to the time he had this hemorrhage he had gradually become worse and could only with difficulty swallow food and liquids. He was not able to take liquids or drink water since the time he had his hemorrhage. He had violent choking spells when he attempted to eat or drink.

Examination.—The patient was much emaciated, had a distressed look, the breathing was labored, the breath sounds roughened, mostly bronchial, there were some fine moist râles throughout chest, and he had a rasping cough.

Roentgen Findings.—The patient was given a mouthful of barium mixture and told to swallow. The fluoroscope showed the meal to go down the esophagus a short distance and then to go through and fill the bronchi, both lower trunk areas and the bronchioles. These were all seen distinctly as the barium filled them. The patient went into a fit of coughing and expelled a considerable quantity of the meal. He was at once rushed to the roentgenographic room, and stereoscopic roentgenograms of the chest were made. The



Roentgenogram of esophagobronchial fistula.

roentgenogram here shown is one of the pair made at this time. The main trunks and branches are easily made out, but they are not shown in the dilated form as we saw them on the screen. Just above the bifurcation there is made out a mass of barium, probably a dilation at the region of the fistula. There was an area of denser lung shadow in the left middle, and the upper trunks looked to be dilated and thickened. The patient was sent to the ward and fed by rectum. Gastrostomy was performed the third day. The patient stood the operation well. On the seventh day the patient died, apparently from pneumonia. Unfortunately necropsy was not obtained.

Laboratory Report.—Sputum negative. Urine negative. Wassermann positive.

COMMENT

This case is interesting because of the value of the stereoroentgenograms obtained, giving the exact anatomy of the lower bronchial trunk areas in the lung of a living subject. I have not been able to find any similar case reported in literature. The primary cause of this esophagobronchial fistula was probably syphilis.

Hume Mansur Building.

A SPECIMEN OF "AUTO-AMPUTATION" OF THE APPENDIX

J. R. Judd, M.D., Honolulu, H. I.

In "Keen's Surgery," v, 741, J. B. Murphy uses the expression "auto-amputation" of the appendix. The specimen illustrated in the accompanying photograph seems to belong to this classification, and is reproduced as a pathologic curiosity.

The patient from whom the appendix was removed was a man, aged 24, with an indefinite history of appendix inflammation.

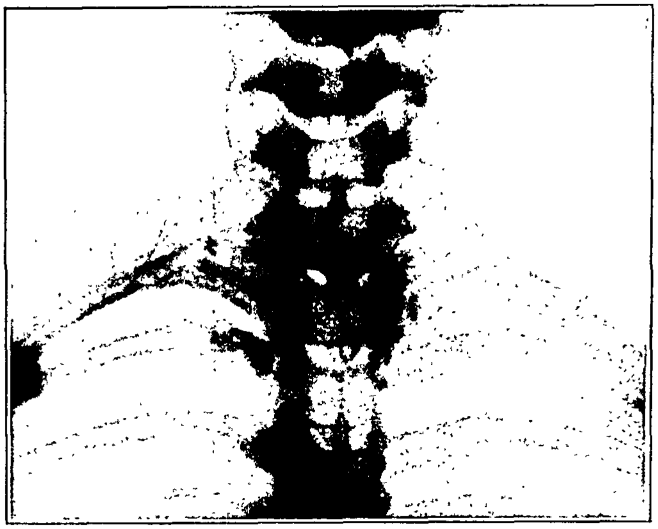
During the course of a kidney operation, the appendix was exposed through the lumbar incision and was brought up into the wound. It was found to be connected with the cecum only by a fine adhesion, so delicate that simply pinching it between the fingers sufficed to separate it. Careful probing failed to disclose any opening into the cecal cavity. The proximal end was also solid. The appendix was 7 cm. in length, not dilated and contained a small amount of mucoid material. It showed the lesions of a chronic interstitial inflammation.

Specimen of "auto-amputation" of the appendix.

CERVICAL RIB AS A CAUSE OF BRACHIAL PAIN

Fred B. Kyger, M.D., Kansas City, Mo.

Cases of cervical rib, while seldom reported, are not uncommon. When the chief complaint is brachial pain, one must always be on guard, as the diagnosis is frequently confused with rheumatism, brachial neuralgia, or neuritis. Miss T., a college student, complained of pain in the right arm and side of the neck. She had been under osteopathic and electric treatment for ten months under a diagnosis of neuritis. The pain had started about one year before in the right arm, and had been growing steadily worse, extending up into the neck and side of the head. She suffered from nervousness and insomnia, and at times the pain was so severe that opiates had to be given.



Cervical rib as cause of brachial pain.

The patient was 21 years of age, and weighed 105 pounds, which she stated was about 10 pounds under her normal weight. Personal and family history were negative. Both parents were living and healthy. Her pulse and temperature were normal. Nothing could be seen on inspection, as there was no especial bulging over the region complained of. She was very tender to palpation above the clavicle and to each side of the cervical vertebra. There was also a firmer resistance to the examining fingers than is normal to that location.

"A pulsating mass above the clavicle means cervical rib nine times out of ten," says Cabot. This characteristic sign, caused by the pulsation of the subclavian artery which usually overrides the rib, was not felt perceptibly in this case. The constant brachial pain with the marked tenderness in that region pointed strongly to cervical rib, and such a diagnosis was given.

The patient returned to her home in Pueblo, and the diagnosis was confirmed by the Roentgen ray, as shown in the accompanying negative taken by Dr. Epler. The patient was subsequently operated on by Dr. Pairs of Pueblo with excellent results.

700 East Thirty-First Street.

Good Food.—What is needed is not so much uniform food laws throughout the country as uniform food definitions for the guidance of those who have in charge the enforcement of the laws. Let us have uniform food definitions that will be accepted by all and then we shall hear very little about the necessity for uniform food laws. If the manufacturers are really sincere and desire to have uniformity other than on a low plane, they can accomplish the most by encouraging the establishment of definitions and standards that will afford protection alike to the consuming public and to the honest manufacturer.—*Bulletin of the North Dakota Agricultural Experiment Station.*

New Instruments and Suggestions

AN AID TO A GOOD FUNCTIONAL RESULT IN ARTHROPLASTIES ON A DIGIT

Paul Gallagher, M.D., El Paso, Texas

In doing my first arthroplasty on a finger, I was impressed with the need of some apparatus which would at the same time give proper exercise to the joint operated on but would be neither cumbersome nor expensive. With this in view, I devised the apparatus shown in the accompanying illustrations.

The arthroplasty was done on the proximal interphalangeal joint of the fourth finger to relieve a traumatic bony ankylosis. As a result of exercise prescribed, two months after the operation, the patient could lift and carry with ease, without assistance and on this joint alone, a weight of 7¾ pounds. Voluntary flexion was present to about 45 degrees and extension to about 170. Any article, such as a pick or ax, could be grasped firmly and securely. In other words, the hand on which the operation was performed is about as good as its normal fellow.

Supervision and encouragement by the surgeon are needed, but I am confident that with some such apparatus fewer fingers need be sacrificed and better surgery will be done.

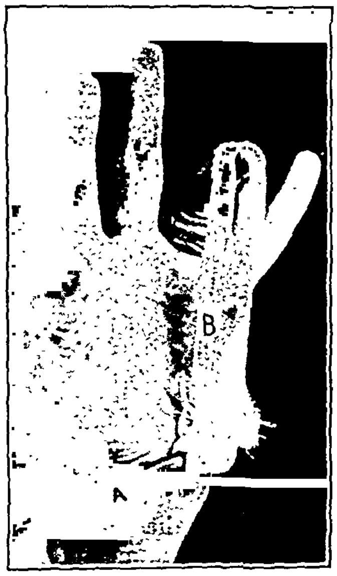


Fig. 1.—Method of obtaining primary passive flexion.

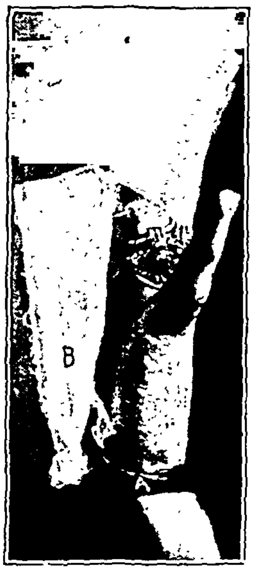

Fig. 2.—Method of obtaining primary passive flexion.

The apparatus consists of a cuff of old rubber glove (*A* in the illustrations), a piece of bandage (*B*) and a thin strip (*C*) about 8 inches long to which are attached by adhesive tape one or more small rubber bands. The number of bands is to be increased from day to day as the need of greater resistance is met.

Figures 1 and 2 illustrate the method of getting primary passive flexion. From day to day the bandage piece is tightened and the cuff slipped up on the arm until flexion is such that the bandage piece will no longer stay on the finger.

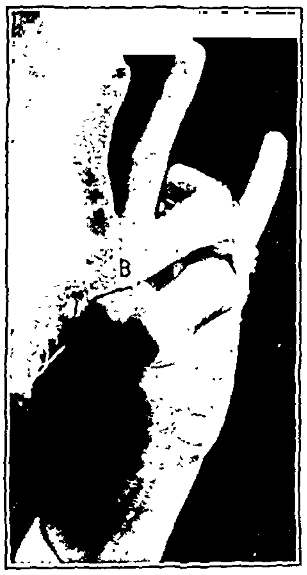

Fig. 3.—The ends of the cuff of the rubber glove are tied to the ends of the bandage.

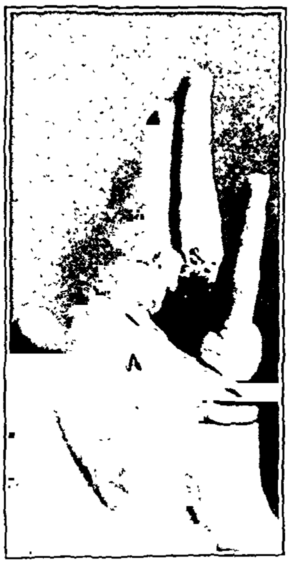

Fig. 4.—Method of obtaining greatest possible passive flexion.

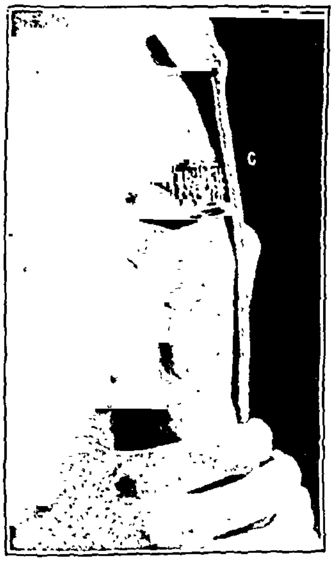

Fig. 5.—Method of obtaining forced flexion and also of developing flexors and extensors.

Figure 3 illustrates the change to be made then and to be persisted in till the piece of bandage, coming around from the back of the hand, can give no greater flexion.

Figure 4 illustrates the method of obtaining the most complete degree of passive flexion possible.

Figure 5 illustrates the method of getting forced flexion and of developing the flexors and extensors too.

I do not believe that the method has been described before, as I was unable to find anything similar when looking up the subject for my own guidance.

AN AUTOMATIC TRANSFUSION APPARATUS*

Morris Kush, M.D.,† New York

In spite of the apparent simplicity of the cannula and syringe methods now used in transfusion, several assistants and more or less elaborate preparations are always needed in order to make the operation go smoothly. With the purpose of eliminating all assistants, and reducing the entire process to as simple a procedure as possible, but still retaining the efficiency of the older methods, the apparatus herewith presented was devised.

The idea of using one syringe in transfusion was first suggested by the Schreiber salvarsan apparatus. Experimentally it was shown that the ball valve was entirely unsuitable for working with blood, owing to the fact that whirring of the valves soon caused clotting. The valve idea, however, was not abandoned, and finally the principle of the sliding valve was utilized in making this machine.

By reference to the accompanying diagram (Fig. 1) the mechanism will readily be understood. Essentially we have a cylinder (*A*) containing a piston (*B*). The cylinder contains two ports (1 and 2), an opening in the base (3), for the escape of air, and a set screw (4). The piston contains a passage way (5) and a milled groove (6). This groove is so built that it receives the set screw, and the latter limits the motion of the piston so that at the end of each excursion the passage way (5, lower end) is exactly opposite either the upper or lower port, and absolutely prevents any rotation. A spring (7) is placed between the piston and the cylinder. This spring is of such strength that it will just support the piston plus an empty 20-c.c. record syringe at the upper port.

The theory of action is as follows: Port 1 is connected with the donor and Port 2 with the recipient. The record syringe is fitted into the passage way (5, upper end). Aspiration on the handle of the syringe raises the piston (*B*) so that the passageway (5, lower end) is opposite Port 1 and permits of the entrance of blood from the donor into the syringe. Depression of the handle of the syringe shifts the piston (*B*) so that the passageway (5, lower end) is opposite to Port 2 and permits of the expulsion of the blood from the syringe into the recipient.

The only criticism which has been made is that clotting will occur because at the end of each cycle the apparatus is not flushed with saline. So far as the valve is concerned, this has been made so accurately that the blood is exposed to a perfectly smooth, continuous passage, and clotting has not occurred. So far as the syringe is concerned, this drawback has been overcome by making use of a method suggested by Dr. C. A. Elsberg. It is well known that to remove clotted blood from a record syringe, all that is necessary is to place it on ice. It was therefore thought possible to *prevent* clotting by keeping the syringe cool. This is done by spraying the barrel with ether from an atomizer during the course of the transfusion. Paraffin-coated catheters with connecting plugs carry the blood between the instrument and the donor and patient. These have been proved capable of withstanding clotting. The ordinary intravenous cannulas of the Kaliski type are used in the veins. The complete apparatus set up and ready for use is shown in Figure 2.

---

* From the Surgical Service of the Mount Sinai Hospital.

† Dr. Kush died, May 27, 1915.

The method of procedure is as follows: The entire apparatus is rendered sterile by boiling, and then the tubes are taken from a supply prepared in advance. The cannulas are introduced into the veins, that in the donor pointing peripherally and that in the recipient centrally. The tubes are connected with the valve, and the syringe, half full (10 c.c.) of normal saline solution, is attached to the piston. The solution is expelled through each tube, leaving an air-free circuit. The trocar is removed from the donor's cannula, and the upper tube leading to Port 1 attached. The lower tube from Port 2 is attached to the recipient's cannula. Transfusion then proceeds by manipulating the handle of the syringe in the usual fashion, the barrel being subjected to the ether spray throughout the entire procedure. Any desired amount of blood can then be transfused.

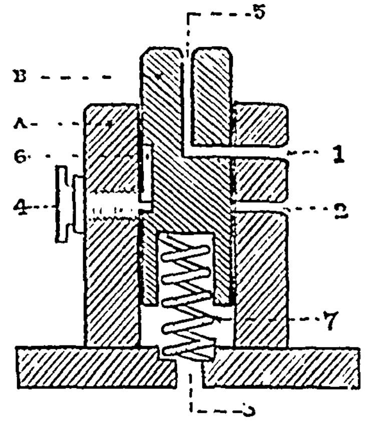

Fig. 1.—Details of automatic transfusion apparatus.

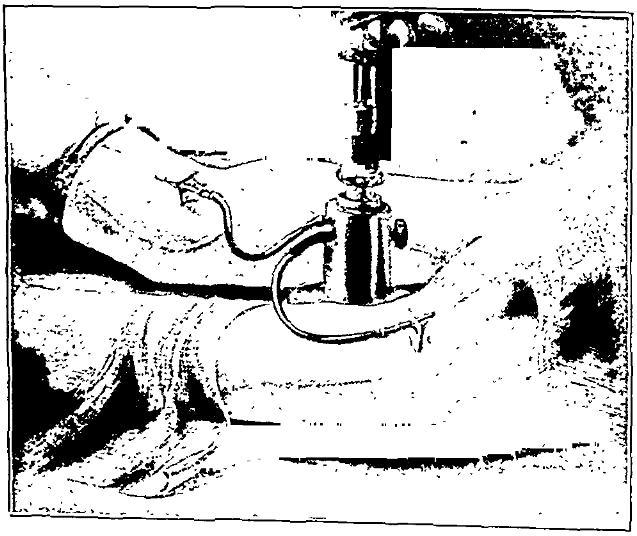

Fig. 2.—Automatic transfusion apparatus ready for use.

Experimentally the device has proved efficient. Several dogs have been transfused, and a number of phlebotomies have been performed. Two successful human transfusions, one of 260. c.c. and one of 160 c.c., have also been performed.[1]

[1] The apparatus here described is manufactured by Tiemann & Co., New York.

A SIMPLE OPERATING MALLET*

Henry W. Meyerding, M.D., Rochester, Minn.

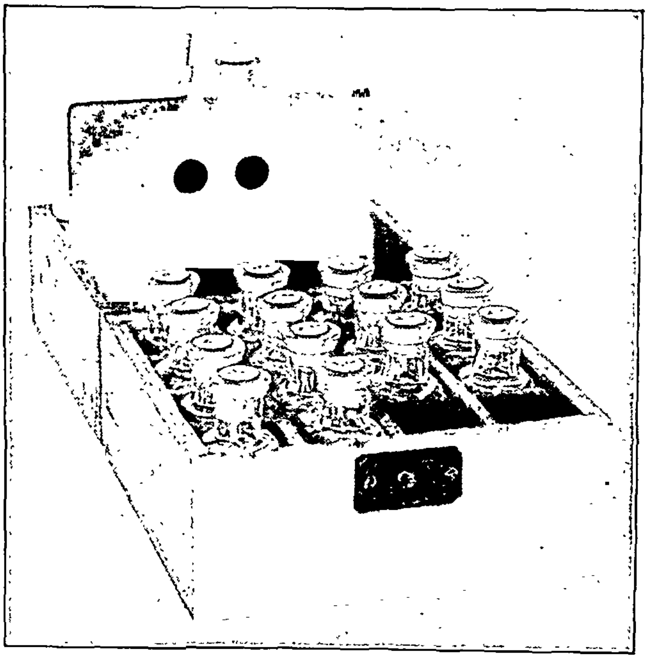
In surgery of the bone it is important to be able to watch the cutting edge of the chisel, and accurately to gage the force of the blow without danger of striking the hand and tearing the glove. The mallet of my design here illustrated has been used with satisfaction for several years in the Mayo Clinic. It is an alloy of zinc, copper and aluminum so composed that the metallic ring of the hammer is avoided, so shaped as to allow a firm grip, and heavy enough to deliver a forceful blow. It measures 8 inches in length, and the diameters are 2½ inches at the head and 1¼ inches at the handle.

Operating mallet.

DEXTROSE COLORIMETER

Philip Atlee Sheaff, M.D., Philadelphia

In The Journal, April 25, 1914, p. 1307, Kleiner describes "A Clinical Method for the Rapid Estimation of the Quantity of Dextrose in Urine." This method has proved of much use to myself and certainly to all others who have availed themselves of Kleiner's suggestions. As a further aid in the technic, the accompanying illustration will make clear a container for the "standard vials" which I have constructed.



Container and screen for standard vials.

---

* From the Mayo Clinic.

The solutions vary by gradations of 0.25 per cent., reaching a maximum of 3.5 per cent.

When in use, the solution to be tested is placed in a fixed position on a shelf behind one of the holes shown in the black screen, while one of the "standard vials" is placed alongside of it back of the remaining opening. Back of both vials is fixed a white opaque glass. When not in use, the black screen and the glass are held securely in the top of the closed box, and the solutions are kept in the dark.

The "standard vials," prepared as Kleiner directed, have changed color in my hands since being made up, shortly after his paper was published, and in the "standard vials" now in use I have omitted adding to the filtrate the ammonium hydroxid solution of Kleiner's formula, and have substituted 1 c.c. of commercial formaldehyd solution to 9 c.c. of the filtrate.

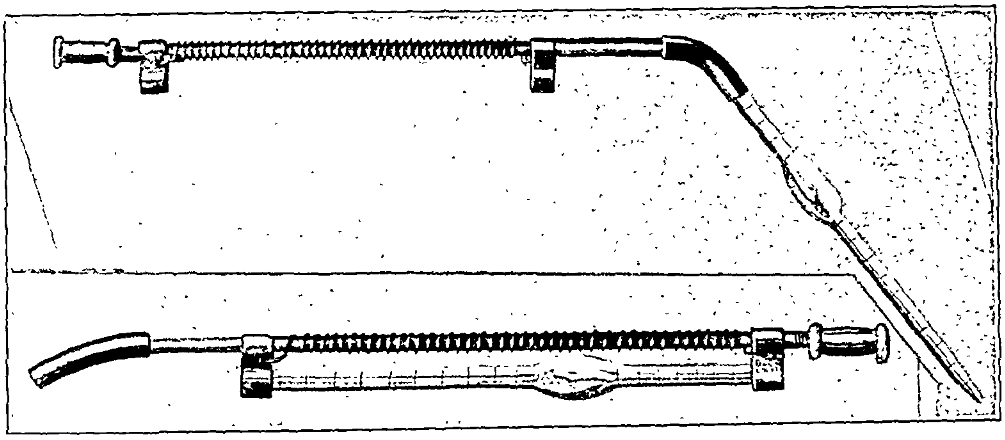
This gives a series of lighter blues, the permanency of which remains to be decided by the test of time.

4008 Baring Street.

A COMBINATION HOLDER AND ASPIRATOR FOR USE WITH THE BLOOD PIPET*

Gordon J. Saxon, M.D., and Louis E. Drummond
Philadelphia

Most clinical laboratory workers have from time to time encountered annoying incidents in connection with the simple procedure of doing a leukocyte or red blood cell count. The rubber tubing has at times been punctured in the process of being used to wrap the ends of the counting pipet, and the contents have escaped in transit from the bedside to the laboratory.



Combination holder and aspirator for use with the blood pipet.

The accompanying illustration shows an implement which is a combination of holder and aspirator for the ordinary blood-counting pipet, and is self-explanatory.

This instrument was made experimentally by Edward P. Dolbey & Co. of Philadelphia and may now be obtained from that firm.

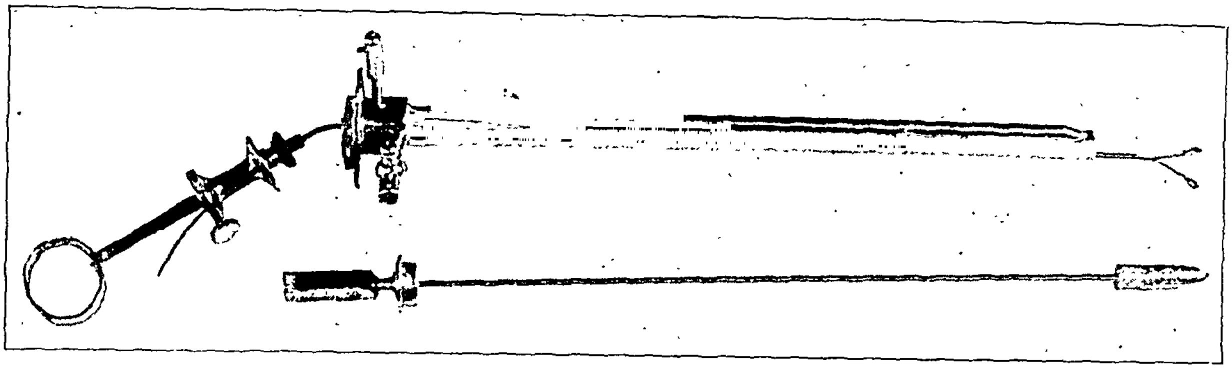
APPARATUS FOR THE REMOVAL OF FOREIGN BODIES FROM THE BLADDER

H. McClure Young, M.D., St. Louis

Any one who has attempted to remove a foreign body from the bladder must have been impressed with the inconvenience attending the use of any beaked cystoscope. The body can be found and grasped with the forceps, but a difficulty immediately arises when we attempt its removal. It is the exception that even a bit of catheter can be withdrawn through the lumen of the cystoscope, and where the greater part of this lumen is already taken up with a lens system, such a procedure becomes practically out of the question. The most rational procedure, therefore, is to remove the cystoscope and forceps together and allow the firmly grasped foreign body to follow after. To such a maneuver, however, the beak of the cystoscope presents a very serious obstacle. The projecting forceps form a continuation of the shaft of the cystoscope, but the beak is set at an angle and will effectually prevent the removal of the cystoscope as long as the forceps are in place. Even when flexible forceps are used, matters are not much better for the reason that the forceps tend to lose their flexibility to a large extent when the jaws are once set.



Apparatus for removal of foreign bodies from the bladder.

The accompanying illustration shows a very simple apparatus designed to overcome these difficulties. It is modeled after an ordinary Koch urethroscope, but is somewhat longer and is provided with a glass window and irrigating cock. It renders possible the dilatation and careful examination of the bladder. The foreign body can then be grasped at the most advantageous point and drawn close up to the mouth of the instrument. If it cannot then be drawn through the lumen, the cystoscope and forceps can be withdrawn together and the foreign body allowed to follow. In this manner it should be possible to remove any object whose passage through the urethra is not in itself an infeasible procedure.

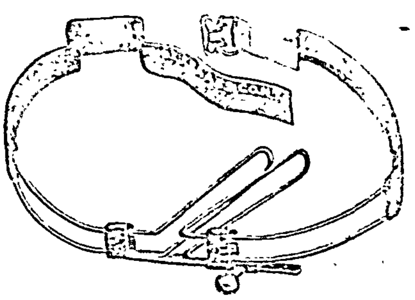
A SELF-RETAINING RETRACTOR FOR THE SUBMUCOUS RESECTION OF THE NASAL SEPTUM

Joseph Eastman Sheehan, M.D., New York

The retractor here illustrated consists of two pieces of steel wire connected by a firm band, which is also of steel, held in position by a screw. The outer face piece consists of malleable material so that one can adjust it to the various conformities of the face.

After it has been placed in position, it is held firm by a linen band which is adjusted to the subject's head. The retractor is particularly serviceable when an assistant is not to be had, and more so when the operation is performed in a sitting posture. The danger of injuring the tissues is lessened, and the operating surgeon has always before him a clear view of the operative field.



Self-retaining retractor for submucous resection of nasal septum.

HERNIA RECORD CARDS

Carleton Dederer, A.B., M.D., Los Angeles
Clinician in Surgery, Los Angeles Department, University of California Medical College

In order to facilitate the history taking and keeping of proper records in hernia cases, I have devised the following form to be printed on the history cards in addition to the usual matter. This card should be used throughout the case in order that the record may be complete. The preferable size is 8½ by 11 inches. This size is suitable for filing in the standard size cabinet.

I. Family history of hernia or hydrocele.
II. Previous hernia history.
III. History of present condition.
    1. Onset.
    2. Cause attributed.
    3. Duration.
    4. Pain.
    5. Spontaneously reducible.
    6. Any general symptoms.
    7. Truss worn.
IV. Examination for hernia, hydrocele and varicocele.
    1. Location and direction.
    2. Appearance of skin.
    3. Shape.
    4. Size.
    5. Character of contents.
    6. Expansile impulse on coughing.
    7. Reducible.
    8. Character of rings.
    9. Normal anatomic structures and position.
    10. Presence of hydrocele, varicocele or inflammation.
V. Treatment.
    1. Truss or
    2. Operation.
        (a) Incision.
        (b) Findings.
        (c) Method of repair.
        (d) Sutures.
        (e) Character of recovery.
VI. Conditions at subsequent examinations.

Therapeutics

ACUTE DIARRHEA

This simple, frequently occurring indisposition may be due to many causes; but whether the diarrhea is due to a poison from without or to a disturbance from within, it is of primary importance to prevent further irritation and further absorption of toxins by free catharsis. This catharsis should be of our own making: the diarrhea is almost never sufficient, especially if a speedy cure is desired. A diarrhea will often cure itself in time, but the disturbance may last for days, and may leave a subacute irritation of the bowels for several weeks. Therefore, the safest and quickest method of curing a diarrhea is to begin with free therapeutic catharsis.

In a few words, the treatment of acute diarrhea, with or without pain, is:

1. Give castor oil (30 c.c. or 1 fluidounce), on black coffee, on water with a little salt undissolved in the bottom of the glass, or on lemon juice; or calomel, 0.20 gm. (3 grains), and sodium bicarbonate, 1 gm. (15 grains), perhaps taken with Vichy; or a Seidlitz powder, Rochelle salt, 20 gm. (5 drams), or magnesium sulphate, 15 gm. (one-half ounce).

2. Allow no food for from twelve to twenty-four hours.

3. Give a good quantity of hot water, or cool water if hot water is refused. Give hot tea if desired.

4. There should be absolute rest on a couch or bed.

5. Two hours after the purgative has been given, begin the administration of bismuth subcarbonate, 1 gm. (15 grains), and phenyl salicylate (salol), 0.30 gm. (5 grains), combined in one powder, and administer such a dose every two hours for ten doses; or, bismuth subcarbonate, 2 gm., and phenyl salicylate, 0.50 gm., may be given every two hours for five doses.

6. If there are much intestinal gas and colicky pains, 2 teaspoonfuls of paregoric, in hot water, should be given every two hours for two or three doses.

7. If the bowels move too many times from the cathartic, $\frac{1}{10}$ grain of morphin sulphate should be given by the mouth, and repeated in three hours, if needed. Large doses of morphin in such a condition are not needed.

8. If the patient is faint, give $\frac{1}{30}$ grain of strychnin sulphate by the mouth, and, if deemed advisable, one-half teaspoonful of the aromatic spirits of ammonia, repeated if necessary.

9. If the intestinal pains are severe, a hypodermic of one-eighth grain of morphin sulphate, with $\frac{1}{150}$ grain of atropin sulphate, might be given. Rarely in this condition is a larger dose of morphin needed or necessary. It is, of course, better to avoid morphin, if possible.

10. If the patient is already faint from the pain and from profuse watery stools before the treatment is begun, it may be best to postpone the cathartic and give a hypodermic of morphin and atropin as above, and perhaps $\frac{1}{40}$ grain of strychnin sulphate. This hypodermic treatment, combined with rest and a hot water bag to the bowels, and perhaps a cup of hot coffee or tea will soon revive the patient. A laxative may be given later, and generally should be, else irritants will remain in the bowels.

11. In from twelve to twenty-four hours hot malted milk, some cereal gruel, milk toast, or mutton broth may be given, and repeated; later a poached egg, and still later a small piece of steak or a lamb chop may be allowed the patient.

12. Bismuth subcarbonate, 1 gm., may be given three times a day for a few days, if thought best, but not for too long, as bismuth tends to accumulate in the bowels, and may cause a new irritation. Frequently a Blaud pill, two or three times a day, is indicated. The diet should be gradually enlarged, fruit and laxative vegetables being the last to be added to the list. The bowels should be kept warm for some days after an apparent recovery.

N. B.: There is no excuse for giving calomel in divided doses, as it causes irritation of the upper bowel. *One does not want Doses "1," "2" and "3" of calomel to be acting and Dose "10" not even yet started.* Therapeutic catharsis is purging, not dribbling. This foolish one-tenth-grain-dose-of-calomel-every-hour fad should be given a decent burial. If it is claimed that calomel in small doses is a bowel antiseptic, then the answer is, Why cause poisoning to produce antisepsis? Salol in small doses is a harmless antiseptic; small doses of calomel may mercurialize the whole system. The late vomiting after an operation is frequently due to the administration of divided doses of calomel.

HEART TIRE

It is now recognized that any infection can cause weakness and degeneration of the heart muscle. The *Streptococcus rheumaticus* found in rheumatic joints is the cause of such heart injury in rheumatism. That prolonged fever from any cause injures the heart muscle is well known, and cardiac dilatation after severe illness is now more carefully prevented. It is not sufficiently recognized that chronic, slow-going infection can injure the heart. Such infections most frequently occur in the tonsils, in the gums, and in the sinuses around the nose. Tonsillitis, acute or chronic, has been shown to be a menace to the heart. Acute streptococcic tonsillitis is a very frequent disease, and the patient generally, under proper treatment, quickly recovers. However, tonsillitis in a more or less acute form, sometimes so mild as to be almost unnoticed, probably precedes most attacks of acute inflammatory rheumatism. Chronically diseased tonsils may not cause joint pains or acute fever, but they are certainly often the source of blood infection and later of cardiac inflammations. The probability of chronic inflammation and weakening of the heart muscle from such slow-going and continuous infection must be recognized and the source of infection removed.

The determination of the presence of valvular lesions is only a small part of the physical examination of the heart. Also, too readily is the heart eliminated from consideration as the cause of the general disturbance because murmurs are not heard. A careful decision as to the size of the heart will often show that it has become slightly dilated and is a cause of the general symptoms of weakness, leg-weariness, slight dyspnea, epigastric distress, or actual chest pains. In many such cases the patients are treated for gastric disturbance because there are some gastric symptoms. There is no question but that gastric flatulence or hyperacidity or a large meal causing distention of the stomach may increase the cardiac disturbance, and the cardiac disturbance may be attributed entirely to indigestion, but treatment directed toward the stomach, while it may ameliorate some of the symptoms, will not remove the cause of the symptoms.

When an otherwise apparently well individual begins to complain of weariness, perhaps drowsiness in the daytime and sleeplessness at night, or his night's sleep is disturbed, or he has feelings of mental depression, or he says that he "senses" his heart, perhaps for the first time in his life, with or without any edemas of the feet and legs, with or without any pains referred to the heart or heart region, we should presuppose that there is a weakening of the heart muscle until we have, by careful examination, excluded the heart as *being the cause of such disturbance.*

Although constantly repeated in books on the heart and articles on cardiac pain, it still is often forgotten that pain due to cardiac disturbance may be referred to the shoulders, to the upper part of the chest, to the axillae, to the arms, and even to the wrists, to the neck, and up into the head, and into the upper abdomen. It is perhaps generally auricular disturbance that causes pain to ascend, but disturbances of the ventricles can cause pain in the arms and in the region of the stomach. Not infrequently disturbances of the aorta cause pain over the right side of the chest as well as up into the neck. Real heart pains frequently occur without any valvular lesion, and also, as necropsies have shown, without sclerosis of the coronary vessels.

While angina pectoris is a distinct, well-recognized condition, pains in the above-mentioned regions, especially if they occur after exertion or after mental excitement or even after eating (provided that a real gastric excuse has been eliminated), are due to a disturbance of the heart, generally to an overstrained heart muscle or to a slight dilatation. Too much or too little blood in the cavity of the heart may cause distress and pain, or an imperfect circulation through the coronary arteries and the vessels of the heart, impairing its nutrition or causing it to more readily tire, may be the cause of these cardiac pains, distress, or uncomfortableness.

So frequently is the cause of these pains, disturbances and weakness overlooked and the stomach or the intestines treated, or treatment is aimed at neuralgias. rheumatisms or rheumatic conditions, that a careful examination and consideration of the part the heart is playing in the causation of these symptoms should be made.

The treatment required for such a heart, unless there is some complication, as a kidney complication or a too high blood-pressure or arteriosclerosis (and none of these causes necessarily prohibit energetic cardiac treatment) is digitalis. If there is doubt as to the condition of the cardiac arteries, digitalis should be given in small doses. If it causes distinct cardiac pain, it is not indicated and should be stopped. If, on the other hand, improvement occurs, as it generally does, the dose can be regulated by the results. The minimum dose that improves the condition is the proper one. Enough should be given, and not too much. Before deciding that digitalis does not improve the condition (provided it does not cause cardiac pain), the physician should know that a good and efficient preparation of digitalis is being taken. Strychnin will sometimes whip up a tired heart and tide it over periods of depression, but it is a whip and not a cardiac tonic. While overeating, all overexertion, and alcohol should be stopped, and the amount of tobacco should be modified, there is no treatment so successful as mental and physical rest and a change of climate and scene with pure air.

Many individuals with these symptoms of cardiac tire think that they are house-tired, shop-tired, or office-tired, and undertake physical exercise, such as walking, climbing, tennis playing or golf playing, to their injury. Such tired hearts are not ready yet for added physical exercise; they should be rested first.

The treatment of this cardiac tire is not complete until the tonsils, gums, teeth and the nose and its accessory sinuses are in good condition. Various other sources of chronic poisoning from chronic infection should of course be eliminated, whether an uncured gonorrhea, prostatitis, some chronic inflammation of the female pelvic organs, or a chronic appendicitis.

Longcope[1] has recently shown that repeated, and even at times one protein poisoning can cause degeneration of the heart muscle in rabbits. Hence it is quite possible that repeated absorption of protein poisons from the intestines may injure the heart muscle as well as the kidney structure; consequently, in heart weakness, besides removing all evident sources of infection, we should give such food and cause such intestinal activity as to preclude the absorption of protein poison from the bowels.

CHRONIC APPENDICITIS?

Many patients with a condition diagnosed as chronic appendicitis, when operated on, are not relieved of their pain, constipation, and general abdominal discomfort. In many cases, with what seems to be positive evidence, both by history and physical signs, of a subacute or chronic appendicitis, the appendix is found normal. In many other cases, the diagnosis is found correct, and relief follows operative removal. The fact still remains, however, that a certain large percentage of appendectomized patients disappoint their physicians by continuing to have pain, which we helplessly attribute to "operative adhesions" and which we "think" will gradually subside.

The diagnosis of chronic appendicitis, like that of many other conditions, should be made only by exclusion. Gallbladder disturbance, prolapsed right kidney, and ovarian inflammation must all be excluded, if possible. Adhesions and bands in the appendix region may perhaps be included in a diagnosis of chronic appendicitis, although a better phrase would be "chronic disturbance in the appendix region." An insufficient ileocecal valve, or an enlarged and movable cecum, as first pointed out by Blake[2] may be the cause of such symptoms as constipation, gas, and distention.

The following should be the rule of procedure before operation is done for chronic pain and disturbance in the right lower abdomen:

1. Careful physical examination should be made to exclude if possible gallbladder, kidney, ovarian, or pelvic causes of the right abdominal disturbance.
2. Carefully studied bismuth pictures of the intestines should be taken.

It should be recognized also that many times no conclusion as to the exact conditions in this region can be made until the abdomen is opened. At the operation the gallbladder, the right kidney, the right ovary and tube should all be carefully studied; bands and adhesions should be sought for and broken up, if possible. Also, it may be wise to operate on a cecum for ileocecal valve insufficiency, or for an enlarged pendant cecum. At least these conditions cause symptoms, and many times proper surgical treatment at the time of the primary operation obviates the necessity of a secondary operation.

The main point of this article is that it is often not sufficient, with chronic pain in the lower right abdomen, to remove the appendix, however abnormal it may be found. Especially if the appendix is found normal (though of course it should be removed), the other conditions that cause abdominal disturbance should be investigated and surgically treated.

New and Nonofficial Remedies

The following additional article has been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Its acceptance has been based largely on evidence supplied by the manufacturer or his agent and in part on investigation made by or under the direction of the Council. Criticisms and corrections are asked for to aid in the revision of the matter before publication in the book "New and Nonofficial Remedies."

The Council desires physicians to understand that the acceptance of an article does not necessarily mean a recommendation, but that, so far as known, it complies with the rules adopted by the Council.

W. A. Puckner, Secretary.

MERCURIALIZED SERUM, Mulford.—A solution of mercuric chloride in normal horse serum, diluted with physiologic sodium chloride solution.

Actions and Uses.—Mercurialized serum, Mulford, is proposed for the treatment of syphilis, particularly the cerebrospinal type. It is an attempt to produce a preparation which, while therapeutically active, possesses comparatively low toxicity and slight local irritative action, and which consequently is adapted to intraspinal use and can be used intravenously without danger of phlebitis.

Dosage.—Intraspinally, 30 Cc. of a solution, the dose containing the equivalent of 0.0013 Gm. (1/50 grain) mercuric chloride, increased, when tolerance is established, to 30 Cc. of a stronger solution, the dose containing the equivalent of 0.0026 Gm. (1/25 grain) mercuric chloride. Intravenously, 2 Cc. of a solution, the dose containing the equivalent of 0.0055 Gm. (1/12 grain) mercuric chloride, increased, if indicated, to 8 Cc. of the same solution, the dose containing the equivalent of 0.022 Gm. (1/3 grain) mercuric chloride.

The H. K. Mulford Company, Philadelphia, Pa. No. U. S. patents or trade-marks.

Mercurialized Serum, Mulford, No. 1.—Each package contains one 30 Cc. ampule, containing the equivalent of 1.3 mg. (1/50 grain) mercuric chloride, with rubber tubing and an intraspinal needle.

Mercurialized Serum, Mulford, No. 2.—Each package contains one 30 Cc. ampule containing the equivalent of 2.6 mg. (1/25 grain) of mercuric chloride, with rubber tubing and an intraspinal needle.

Mercurialized Serum, Mulford, No. 3.—Each package contains ten 30 Cc. ampules, each containing the equivalent of 1.3 mg. (1/50 grain) mercuric chloride, with rubber tubing and an intraspinal needle.

Mercurialized Serum, Mulford, No. 4.—Each package contains ten 30 Cc. ampules, each representing 2.6 mg. (1/25 grain) of mercuric chloride, with rubber tubing and an intraspinal needle.

Mercurialized Serum, Mulford, No. 5.—Each package contains 8 Cc. mercurialized serum, Mulford, containing the equivalent of 22 mg. (1/3 grain) of mercuric chloride in a syringe graduated in fourths, with needle.

Mercurialized Serum, Mulford, No. 6.—Each package contains ten syringes graduated in fourths, each containing 8 Cc. liquid which represents 22 mg. (1/3 grain) of mercuric chloride.

Mercurialized serum, Mulford, is prepared by adding to a solution of mercuric chloride sufficient normal horse serum to dissolve the precipitate first formed and then diluting to the desired volume with physiologic sodium chloride solution.

OBJECTIONABLE FEATURES OF GARBAGE DISPOSAL

In almost every large community there are plants for the disposal of garbage and offal; they represent a feature of the conservation processes which economic conditions have made necessary. The work includes the recovery of grease and the manufacture of tankage, a product at first used solely as a fertilizer but now beginning to enter into the feed of the domestic animals. The processes are not infrequently attended with the production of odors and sometimes of dust of a disagreeable nature, leading to complaints and raising questions of public hygiene and comfort. Where waste-disposal engineers are not available, the expert advice of physicians is drawn on. Testimony is sought as to the alleged nocuous or innocuous character of the subject of complaint; but, owing to the meager character of the information on this topic possessed by most of us, the outcome of the testimony is often quite contradictory.

Some of the offensive odors from the fat rendering or reduction plants originate from the raw "green" garbage. These odors, as well as certain others arising in the manipulations, are of a rather local nature. Other odors from some of the treating methods may be far more objectionable in that they are capable of causing discomfort several miles away. How to avoid or counteract these difficulties in the economic handling of large quantities of very low grade materials, particularly in the neighborhood of such places as Chicago and New York, is a problem that has taxed the ingenuity of many experts. The Central Testing Laboratory of New York City has lately made a chemical study of the nature of the odors and dust in garbage reduction plants and also the present and possible means of treating them.[1] In the reduction works located near to inhabited sections, garbage must be transported in closed scows or cars; the handling of the garbage, both raw and in process, and other obnoxious treatments should properly be carried out inside of buildings in which the odors can be properly disposed of. In many cases the ventilating air can be drawn through "scrubbers," which are devices for washing the gases with water to dissolve or retain some of the objectionable constituents. Afterward this partly purified air can be passed through devices for scenting it with wood-tar oils or coal-tar. Systems of this nature are successfully used in treating packing-house air. For many persons the sense of smell seems to be the guardian of health, so that the "covering up" or substitution or confusion of odors is quite as comforting as the more rational elimination or destruction of the offending respiratory invader.

In the manufacture of tankage, garbage is necessarily heated in large containers for several hours, usually with the aid of live steam. It is the vent gases from these "digesters" that have odor of more than local importance. According to Mahr and Kraft,[1] the mechanically carried over substances removed by the condensers are principally mineral matter, fats and fatty acids. The volatile substances in the vent gases which are condensable or absorbable in water include alcohol, acetic acid, carbon dioxid, essential oils and sulphur compounds. Of these constituents, the latter two are important from the standpoint of odor. The extremely nauseating odor of the uncondensable vent gases appears to be due to sulphur compounds and other nonsulphur-containing substances, possibly essential oils.

In some plants, very high temperatures are used for destroying the odors and uncondensable vent gases from garbage digesters. Thus they are sometimes sent through the fires required in the devices for drying the tankage. A method of deodorizing packing-house air by means of sulphur dioxid has been said to give good results. According to Mahr and Kraft, it is possible that the sulphur dioxid, formed by heating the vent gases, could be reconducted to the jet condensers, and in this way a deodorization of the condenser water brought about.

However efficient the elimination of the nauseous products of the garbage reduction processes themselves may be, they do not exclude the necessity of maintaining in a cleanly way all plants where garbage is collected, stored and treated. Winds passing over a filthy plant may take up considerable residual odor, even when no garbage is present or in process. The New York experts emphasize the fact that to eliminate this source of trouble, garbage plants should be of the most sanitary construction to permit washing and prevent material lodging in crevices. The cement of concrete floors is readily attacked by the "stick liquor" and garbage, and wooden floors are sometimes put down. As may be easily understood, these soon become of a very objectionable nature and cannot be well cleaned. A concrete floor with a frequently renewed tar coat or one of asphalt would be a great improvement on the wood.

---

To the layman it must seem strange that until recently so little serious study has been given to problems which involve inevitable sources of discontent and occasions for remonstrance in our larger cities. As in the case of the smoke nuisance, the authorities have been content to obey the law of inertia until popular demand has precipitated an immediate and hasty examination of phenomena which have long demanded more careful and detailed scientific investigation. We have become accustomed to a conventional shabby treatment of applied science as a factor in community life and economic progress, but this sometimes ceases to be a joke.

THEORY AND PRACTICE

In his presidential address before the British Association for the Advancement of Science on the subject, "The Common Aims of Science and Humanity," Prof. Arthur Schuster[1] discusses the age-old ever-recurring problem of the comparative value of theory and practice for accomplishment in life. Much is said in our time of the difference between the academic scientist and the man of affairs. Professor Schuster speaks of England, but some of his remarks apply very aptly to conditions in America; for instance, he says that "sometimes we are recommended to hand over the affairs of the nation to men of business; sometimes we are told that salvation can only be found in scientific methods." An analysis of these type characterizations does not reveal the opposition that is often supposed to exist between them. Schuster justly insists that "every method that leads to a correct result must be called a scientific method," and that therefore when "one man calls for the conduct of affairs on 'business lines' and the other clamors for scientific methods, they either want the same thing or they talk nonsense."

This discussion is of particular interest to physicians because of the unending difference of opinion as to the relative value of theory and practice in medical education. In this, as in everything else, truth lies not at one of the extremes, but between them. Schuster says:

"The most fatal distinction that can be made is the one which brings men of theory into opposition to men of practice, without regard to the obvious truth that nothing of value is ever done which does not involve both theory and practice; while theory is sometimes overbearing and irritating, there are among those who jeer at it some to whom Disraeli's definition applies: 'the practical man is the man who practices the errors of his forefathers.' With refined cruelty Nemesis infects us with the disease most nearly akin to that which it pleases us to detect in others. It is the most dogmatic of dogmatics who tirades against dogma, and only the most hopeless of theorists can declare that a thing may be right in theory and wrong in practice."

"Common sense" is another stereotyped expression which Schuster is inclined to challenge. Huxley is often quoted as declaring that science is organized common sense, but Schuster cannot find a definition of common sense that fits the phrase. "Sometimes the word is used as if it were identical with *uncommon* sense, sometimes as if it were the same thing as common *nonsense*." He suggests that in its best aspect it is that faculty which recognizes that the obvious solution of a problem is frequently the right one. It must not be forgotten, however, that obvious explanations often are quite wrong and that any scientific reason to the contrary, when supported by good observations, makes the common-sense explanation of no value. This is true even with regard to things as to which there is almost universal agreement among mankind. The obviousness of the sun going round the earth has no weight when it comes to the scientific demonstration that the earth goes round the sun. The practical man, proud of his common sense, comes around to the theorist's view in this matter when he knows enough.

All advance in science comes from a combination of theory and practice, or rather, from a successful application of theory to practice. In this way what seemed to one generation the climax of theory becomes to the next generation only a very obvious practical scientific advance. There is no real opposition between correct theory and correct practice. Practice cannot dispense with theory, and theory is sure to become unreal and fallacious when not reduced to practice in some way. The greatest discoverers — Galileo, Pasteur, Kelvin, Lister and practically all the great discoverers in medicine — are always theorists and men of action as well. The opposition between theory and practice is a myth, fostered largely by the bungling theorist who is unable to put his theories into practice, and by the bungling "practical man" who is unable to express the theory which underlies his practice.

THE PANCREAS, AND SUGAR IN THE BLOOD

In recent discussions of the causes of diabetes, two theories have gained prominence. The Journal has referred to them[1] as the over-production and non-utilization theories, respectively, using these terms in relation to the sugar factor, which naturally forms the essential theme for consideration in this disease. Whether or not it is agreed that the disturbance in the carbohydrate metabolism appears to represent a loss of power of oxidizing glucose, there is one fundamental fact about which no difference of opinion can exist.

---

[1] Schuster, A.: Science, Sept. 24, 1915, p. 397.

[1] The Metabolism in Experimental Diabetes, editorial, The Journal A. M. A., Sept. 4, 1915, p. 878.

In diabetes, the sugar content of the blood is higher than normal and is variable in amount, and, when it is sufficiently high, the glucose escapes through the kidneys into the urine. Hyperglycemia precedes the glycosuria.

At the department of physiology and pharmacology of the Rockefeller Institute for Medical Research, Kleiner and Meltzer[2] have made a series of experimental observations that throw a somewhat different light on the subject of diabetes. Apparently certain striking differences in behavior occur between normal animals and those rendered diabetic by excision of the pancreas, a procedure which is familiarly known to result in glycosuria. Under physiologic conditions, sugar is liberated into the circulation from the liver, where it is stored as glycogen. If this function is imitated in an indirect way by the infusion of sugar solution directly into the circulation, the carbohydrate speedily finds its way out of the blood in some manner or other. Even a very large surplus of glucose will disappear from the blood stream under these circumstances. When the amount is large, part of the sugar is excreted through the kidneys, and part finds its way into the tissues. Before long the glucose content of the blood reaches nearly the same level which it had before the injection. Even in the absence of the kidney function, in nephrectomized animals, for example, the glucose returns to the previous level in about the same length of time, affording a striking example of the ability and readiness of the circulation of a normal animal to rid itself of a large surplus of sugar.

Quite different is the outcome of the introduction of sugar into individuals from which the pancreas has been removed. In such cases the blood is strongly hyperglycemic even before the sugar infusions. Kleiner and Meltzer found here, in contrast with what has just been recited, that the glucose content of the blood is not reduced promptly after the introduction of sugar. Apparently the removal of the pancreas interfered with the power of the circulation to rid itself readily of a surplus of glucose. The possible ability of the liver to provide the circulation with a greater supply of glucose in the absence of the pancreas can certainly be no important factor in these results. The investigators believe these new experiments to show that, in the presence of the pancreas, the circulation rids itself easily of intravenously introduced glucose, but that it is unable to do so satisfactorily in the absence of the pancreas. On the basis of these facts, Kleiner and Meltzer ask whether it is not plausible to assume, further, that the pancreas exerts exactly the same influence when the glucose in the circulation is being supplied in some other manner than by a buret into a vein — by the liver, for instance — through its connections with the circulation. In other words, do not these experiments make the assumption plausible that pancreatic hyperglycemia is due to the fact that, in the absence of the pancreas, the circulation is unable to dispose properly of the dextrose which it receives in normal amounts from the liver?

This is not all. The actual participation of the pancreas in the normal regulatory function is further suggested by the fact that the ability of the circulatory apparatus of animals to get rid of a surplus of glucose injected intravenously — a function which is impaired in the absence of the pancreas — can be temporarily restored by an intravenous injection of a pancreatic emulsion. Furthermore, such a procedure is also capable of reducing the hyperglycemia due only to depancreatization to a normal level of the sugar content of the blood.

It is too early to speculate extensively on the nature of the factors here involved. These interesting observations add one more link to the chain of evidence regarding the conspicuous performance of the pancreas in the disposal of sugar in the organism. Again, it becomes obvious that such effects of the pancreas must be of a chemical rather than a nervous character.

THE SURGICAL TREATMENT OF NEPHRITIS

Since Reginald Harrison, in 1896, reported an unexpected improvement in the symptoms of acute and subacute nephritis after incision of the renal capsule, operation has been performed with apparent success in many cases of nephritis of various types. Ruge,[1] who carefully reviews the literature, points out that the examination of kidneys exposed in these operations, as well as recent experimental work, in some ways have revolutionized our ideas about nephritis. Thus, it has been established that albuminuria, even when accompanied by casts and red blood cells, does not necessarily indicate nephritis as the term is understood usually, for purely mechanical factors may so interfere with the renal filter as to produce the urinary picture of nephritis. Conversely, in chronic nephritis as determined by microscopic examination, all symptoms may be absent, or a severe hemorrhage or colic may be the first and indeed the only sign. Of especial interest are observations to the effect that acute infection may develop in one kidney, or part of one kidney, and later be followed with injury to the healthy tissue by so-called nephrotoxic substances. The results of experiments indicate that increased blood pressure is not produced by mechanical changes in the renal vessels, but is probably due to resorption of degenerating renal epithelium.

In acute nephritis an explanation of the good results of capsular incision and capsular removal is not difficult, since pressure on swollen and inflamed tissue is relieved. After injecting diuretic solutions in cats Gawrilow obtained from two to four times as much blood in the renal vein, and from two to four times as much urine was collectible from the decapsulated as from the untouched kidney. The pressure of the capsule seems to establish a vicious cycle by increasing the circulating disturbance and thus causing even greater injury to the epithelium. In experimental toxic nephritis in dogs, Onorato reports recovery in five out of eight cases in which decapsulation was performed, while all the animals not operated on died. If these observations are in harmony with the conditions in man, certainly surgical treatment is indicated in all acute conditions in which conservative treatment does not succeed. In eclampsia, the variable severity of symptoms renders difficult the comparison of statistics. The general attitude of the observers now seems to favor decapsulation in severe cases. Sippel states that the operation is indicated when threatening symptoms of severe nephritis remain after the uterus has been emptied. After ureteral catheterization the kidney which shows greater injury should be treated. If there is no difference, both may be decapsulated if the condition of the patient permits. The operative mortality is relatively slight. Convulsions, it is said, usually stop at once and coma rapidly disappears.

---

[1] Ruge, E.: Ueber den derzeitigen Stand einiger Nephritis-Fragen und der Nephritis-Chirurgie, Ergeb. d. Chir. u. Orthop., 1913, vi, 503.

In nephritis following acute infections surgical treatment has not come into vogue, probably because surgeons do not see many such cases. Operation is held to be indicated when anuria or uremia point toward an increase in intrarenal pressure. Pousson, in 1904, reported operations in 37 postscarlatinal cases, with 6 deaths. Since then nearly twice as many cases at least have been reported. Of course, nephrotomy in such cases is indicated when the presence of an abscess is suspected. When bacterial emboli cause diffuse infiltration or abscess formation, nephrotomy, always preceded by ureteral catheterization, is the operation of choice if the condition of the kidney does not demand its removal. Kümmell has reported 28 cases, 17 nephrectomies and 11 nephrotomies with only 3 deaths. Tenderness and muscular defense in these forms of nephritis are important signs.

The good effects of decapsulation in chronic nephritis are harder to explain. Experiments indicate that in certain cases collateral circulation may be established. That the consequent maintenance of function is at best a temporary one, may explain the conflicting reports. Clinically, improvement and recovery have been noted in many instances. Guiteras, in 1904, reported decapsulation in 120 cases of chronic nephritis, with clinical recovery in 16 per cent., improvement in 40 per cent., and death in 23 per cent. In Edebohls' 102 cases, reported in 1909, 49 patients died within five years, 33 were permanently cured, 11 improved, and 6 remained uninfluenced by operation. Kümmell, in 1912, reported 26 cases with definite improvement in 14. In general, it would seem that when long internal treatment shows slight or no improvement, or if the condition grows worse, decapsulation might be tried. Anuria and uremia in chronic nephritis, in the opinion of most authors, are favorably influenced by surgical treatment. Thus, Uteau found that, in 300 cases of anuria under various methods of treatment, 75 per cent. of the patients treated surgically before the fourth day and 58 per cent. so treated between the fourth and sixth day recovered. Decapsulation, usually unilateral, seems to be the operation of choice.

In renal hemorrhage, considered most commonly as caused by chronic nephritis, differential diagnosis is difficult. If conservative measures fail operation is indicated. While there is no agreement as to the operation of choice, nephrotomy is preferred, according to Ruge, when the diagnosis is in doubt. Kümmell has reported 16 cases, 4 nephrectomies, and 8 nephrotomies, and 4 decapsulations, with one death.

In the nephralgia of chronic nephritis, often combined with hemorrhage, other signs may be absent. The colic which is not at all characteristic is probably due to capsular compression of a swollen kidney. The diagnosis is usually established by exposure and section of the kidney with examination of the pelvis. Kümmel has reported 13 cases, 4 decapsulations and 9 nephrotomies, in 12 of which the patients afterward remained free from pain as long as observed.

From what has been said it appears that it is justifiable to center interest on this comparatively new field of surgery because it awakens hope of benefiting conditions which respond but little to internal treatment, and because of the light it throws on the pathology of nephritis.

DEFENDING THE GREAT AMERICAN FRAUD

Most of the fellows and members of the American Medical Association are aware of the fact that the Chattanooga Medicine Company and its chief owner, John A. Patten, manufacturers of Wine of Cardui, have sued (1) the American Medical Association and the editor of The Journal for $300,000, (2) Dr. Oscar Dowling, President of the Louisiana State Board of Health, for $25,000 and (3) *Harper's Weekly* for $200,000. Comparatively few realize, however, that the "patent medicine" interests of the country are spending money lavishly in a desperate effort to win a suit on whose outcome, they consider, depends the very life of the nostrum business. We have, at different times, given our readers an insight into some of the methods pursued in this case, especially in connection with the employment of detectives for the apparent purpose of manufacturing "evidence."

To refresh the memory it is but necessary to refer to the case of the Limestone County (Ala.) Medical Society.[1] There it was strongly intimated that not only the society, but also the individual members would be sued if the resolutions passed by the society condemning the methods of the Chattanooga Medicine Company were not rescinded. The episode of Detective Smith is also in point. A man who posed as a journalist called on Mr. Samuel Hopkins Adams in New York and on Dr. Bolduan of the New York Health Department. He professed to be seeking information for an article he wished to write to show how prohibition in the South was driving the people of that territory to use alcoholic "patent medicines." Smith came to Chicago and, giving as his references the names of Mr. Adams and Dr. Bolduan, attempted to get an interview with the member of The Journal staff who has charge of the Propaganda Department. Failing to get the interview he left town, stating that he could be reached by mail in Indianapolis, but actually going to Chattanooga. Then there was Barron, who posed as a "western business man" stopping in Chattanooga. It was he who assiduously cultivated the friendship and hospitality—later betraying them—of the Chattanooga pastor who lost his pastorate after he had dared lift his voice against the iniquity of the Wine of Cardui traffic.

But this by the way. The object of this comment is to call attention to an interesting article in the current (October 2) issue of *Harper's Weekly*, wherein are described the activities of some of the horde of detectives employed in this case. We suggest that physicians who have the interest of the public health and the medical profession at heart buy a copy of this week's *Harper's*. Under the title, "Patten in Pink Whiskers," the story gives in detail the experience of "Operative No. 48," a detective who threw up his job in disgust at the work he was expected to do for the "patent medicine" interests. How the private papers of the secretary of the Limestone County Medical Society were ransacked; how the minutes of that society were purloined and copied; how the Chattanooga pastor was dogged by detectives and private conversations taken down in shorthand by stenographers hidden from view—these are some of the things described by "Operative No. 48" in the *Harper* article. Read in connection with The Journal's articles on the Wine of Cardui case,[1] it gives a very good idea of the methods to which the "patent medicine" interests will descend in their attempt to protect their noisome brood and to discredit the medical profession.

Those who in the past have built up huge fortunes by swindling the sick, sense the downfall of their business that is bound to follow the publicity that has been given it by the American Medical Association and other agencies. Really the Wine of Cardui cases are not simply "Chattanooga Medicine Company *vs.* The American Medical Association, Oscar Dowling and *Harper's Weekly;* they are "The Great American Fraud *vs.* The Medical Profession and the Public."

Current Comment

NEUTRALITY REGULATION DURING PREGNANCY

In a recent discussion of the subject of acidosis,[1] attention was called to the seemingly paradoxical statement that, despite the undue production of acid substances which goes on in certain disturbances of metabolism, of which diabetes is a classic example, the regulatory power of the organism nevertheless prevents any marked changes in the reaction of the circulating blood. Pregnancy furnishes a more physiologic instance of an acid-forming tendency provided by nature. It is attended by symptoms which are currently regarded as indicative of a degree of acidosis; and inasmuch as this ordinarily falls within the range of what may be regarded as a fairly normal function, the acidosis of pregnancy should afford an excellent opportunity to study the relative participation of the physiologic regulatory devices for preserving neutrality in the organism. These include, as we have pointed out before, an increased production of ammonia from protein products to neutralize the acid products, a decreased concentration of carbon dioxid in the blood (and alveolar air) owing to its displacement through the agency of the augmented acid; and an increased elimination of acid radicals by way of the kidneys. Which, if any, of these factors are brought into play under the conditions of pregnancy? Hasselbalch and Gammeltoft[2] of Copenhagen have carefully investigated this question by making comparisons of the various functions concerned in the same persons during and after pregnancy. It was found that the hydrogen ion concentration of the blood of gravid females is not different from that of other nongravid individuals of either sex. Whatever unusual production of acid may arise as the outcome of the pregnancy is evidently promptly taken care of by the regulatory mechanism. This is in part accomplished by the ammonia-producing activities, for the percentage output of ammonia in the urine is somewhat higher in the pregnancy period. More striking, however, is the decrease in the tension of carbon dioxid in the blood, which seems to serve in larger measure to prevent any rise in the true acidity. The increased genesis of acid substances, whatever they may be and however produced, is compensated by the expulsion of carbonic acid gas through the lungs and a resulting lower tension thereof in the blood. A fixed acid replaces one more readily expelled. Altered respiration plays a part in the process. The stability or constancy of the reaction of the blood under conditions such as disease and pregnancy, which represent pronounced departures from the usual routine of acid formation in the body, is one of the most interesting facts of physiology. Highly sensitive tissues like the nervous structures are thus spared the irritation of even slight alterations of hydrogen ion concentration. Failure or insufficiency of the regulation brings severe manifestations of disease. This seems to be the case, according to a few experiences of the Danish investigators, in that puzzling condition described as eclampsia.

THE SURVIVAL OF BACILLUS BULGARICUS IN THE ALIMENTARY TRACT

One aim of the procedure which has somewhat tauntingly been termed the sour-milk therapy is to establish the predominance of organisms of the *Bacillus bulgaricus* type in those parts of the intestine in which the products of their activity will repress undesirable putrefactive changes in the alimentary contents. The group of organisms which includes the one specially recommended and found in fermented milk is distinguished by the ability of its members to grow in mediums containing considerable amounts of acid. In a widely quoted research, Herter and Kendall[1] found that by feeding a monkey for two weeks exclusively on milk fermented with *Bacillus bulgaricus* (but containing also some yeasts) it was possible to maintain an acid reaction throughout the digestive tract. The acid reaction was more pronounced above the ileocecal region than at this region or below it. The acidity decreased progressively from the ileocecal region to the anus. Lactic acid was detectable at every point in the digestive tract that was tested, the reaction growing less marked below the ileocecal region. Exclusive feeding for two weeks with milk fermented with *Bacillus bulgaricus* failed to establish the predominance of this organism in the ileocecal region or in the large intestine. In the latter situation, the number of bacilli of this type was relatively small and decreased toward the anus. Thus, in the regions characterized by most active putrefaction, the lactic acid bacilli failed to establish themselves in relatively large numbers. The experimental data in this field deserve considerable attention because of the widespread employment of these bacterial cultures along with the diet in American homes, either with or without the sanction of physicians. The latest of numerous contributions, by Dr. Alfred H. Raehe[2] of the Cornell University Medical College in New York City, brings added evidence that the *Bacillus bulgaricus* cannot become adapted to the lower human intestine. It is still quite possible that such an organism might be able to adjust itself to the conditions prevailing in the duodenum and jejunum, but be unable to survive in the lower intestine, and thus be absent from the stools. A limited survival in the upper intestine of monkeys is apparently possible. This, however, does not adequately fulfil the foremost purpose of those who recommend its use to check the growth of putrefactive bacteria.

THE COLLAPSE IN DIPHTHERIA INTOXICATION

Recent investigations in which exact methods of observation have replaced the clinical guesses of an earlier period make it evident that the haphazard explanations of the circulatory failure and collapse so frequently encountered in diphtheria are not tenable. In so far as they merely charge the heart with some vague disturbance of function, these hypotheses have little in fact to support them. That the vasomotor center is not impaired in diphtheria intoxication may be taken as demonstrated.[1] Two important assumed causative factors are thus excluded. In the pharmacologic laboratory at the University and Bellevue Medical College, New York, Myers and Wallace[2] have examined the possibilities of involvement of tissues other than the heart or vasomotor center. The reactions of the larger blood vessels in intoxicated animals were found to respond to stimulation in essentially the same way as did the arteries of unpoisoned subjects. It may be concluded from this that neither the vasomotor mechanism nor the muscle tissue in the larger arteries is affected to an appreciable extent by the diphtheria toxin. The prominence of gastro-intestinal symptoms in animals poisoned with the products of the diphtheria bacillus and the pathologic picture of the small intestine directed attention to the possible involvement of this region. The intestinal epithelium shows early coagulation necrosis; in the liver the capillaries show a widespread destruction; there is marked congestion in the terminal arteries of other abdominal organs. Myers and Wallace emphasize the significance of these structural changes in the different organs and contend that the engorgement of the mesenteric vessels would offer a sufficient explanation for the low blood pressure. An examination of the intestine as an independent organ has shown, further, that its blood vessels fail to respond in the normal way to the stimulus of drugs like epinephrin, after the subject has been subjected to the intoxication. From such facts it is concluded that the chief factor concerned in the circulatory collapse in poisoning from the diphtheria toxin is the arteriole and capillary dilatation.

Breast Feeding.—Efforts to control the flow of milk which do not take into account the periodic character of its secretion are likely for the most part to end in failure. To this fact must be attributed much of the strength of a very widespread conviction that lactation is a most unreliable function. In the course of many observations from which these notes were constructed, no fact stood out with more prominence than the completely erroneous nature of this belief.—Harold K. Waller, M.B., *Jour. Obst. and Gynec. Brit. Emp.*, February, 1915.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

ARKANSAS

Survey of Feebleminded of the State.—The Arkansas Commission for the Feebleminded has received notice from the Eugenics Record Office, Cold Spring Harbor, N. Y., that Dr. Harry W. Crane of that institution has been designated to carry on that part of the survey of the feebleminded in Arkansas, in which the Eugenics Record Office had previously agreed to assist. Dr. Crane arrived October 1 and began the study and classification of the inmates of the state charitable and penal institutions. The next work to be taken up will be a survey of the public schools to ascertain how many and what percentage of the children reported as backward are really mentally defective.

IDAHO

Medical Board to Meet.—The State Board of Medical Examiners will hold its next session in Wallace, October 5 and 6.

Personal.—Dr. George E. Hyde, formerly medical superintendent of the Idaho Insane Hospital, Blackfoot, has moved to Salt Lake City.——Dr. J. Eugene S. St. Jean, Wallace, had a narrow escape from injury when his automobile went over a 50-foot embankment at Mullan. He escaped, however, with only a bruise of the right knee.

Society News.—A medical society has been organized for the five counties of Twin Falls, Gooding, Lincoln, Minidoka and Cassia. At the meeting for organization at Twin Falls, the committee in charge was composed of Drs. Joseph Fremstad, Burley; Joseph N. Davis, Kimberly; and Drs. A. H. Dunn, Truman O. Boyd and Hubert W. Wilson, Twin Falls.——At the meeting of the Tri-County Medical Society for Blain, Gooding and Lincoln counties held in Hailey, recently, Dr. Simons, Wendell, was elected president; Dr. A. A. Higgs, Soldier, vice president, and Dr. Charles F. Zeller, Shoshone, secretary-treasurer.

ILLINOIS

Opening of Schools Postponed.—September 20, at DuQuoin, the opening of the schools was again postponed on account of the development of several new cases of diphtheria. The disease had prevailed for several weeks in the community and a number of deaths had occurred.

Foot and Mouth Disease.—LaSalle, Bureau and Putnam counties were placed under quarantine, September 25, on account of foot and mouth disease having been found in two herds in LaSalle County.——On account of the presence of foot and mouth disease on the Louis F. Swift farm in Lake County, the deer on this farm were killed, September 28.

Typhoid Fever.—Typhoid fever is reported to be epidemic in Menard County where 110 cases have been reported. The secretary of the State Board of Health has sent two of his assistants and three sanitary engineers to aid in the combat against the disease.——Dr. Patrick M. Kelly, superintendent of the Kankakee State Hospital, has ordered that all the employees and patients in the institution, nearly 4,000 in number, be inoculated against typhoid fever.

Personal.—Dr. John C. Foley and family, Waukegan, and Dr. and Mrs. John L. Taylor and family, Libertyville, returned from an automobile trip to the Pacific Coast and back, September 19.——Dr. John F. Bell, Elgin, was run down by a bicycle, September 15, and sustained severe bruises.——Dr. George A. Zeller, Peoria, alienist of the State Board of Administration, has been appointed a member of the board.——Dr. J. F. Echard, Streator, is reported to be seriously ill in the Streator Hospital with inflammation of the stomach and bowels.——Dr. Clarence A. Wells, Quincy, is made chief beneficiary of Mrs. Nellie A. Ward, deceased.——Dr. Harry L. Kampen has been elected president; Dr. Ralph Graham, vice president, and Dr. Charles P. Blair, secretary-treasurer, of the medical staff of the Monmouth Hospital.——Dr. Chester H. Latham, Pecatonica, who has been seriously ill in St. Anthony's Hospital, Rockford, is reported to be convalescent.

Chicago

Meeting of Society of Medical History.—The Chicago Society of Medical History will meet at the Hotel Sherman, Wednesday evening, October 13. Papers will be read by Dr. Fielding H. Garrison, Washington, D. C., and Dr. Arnold Klebs on Leonardo Da Vinci and Vesalius.

Personal.—Drs. Albrecht Heym, Sydney Kuh and George W. Hall have been appointed members of the attending staff of the Psychopathic Hospital, connected with Cook County Hospital.——Dr. I. N. Miller has moved to Kewanee, Ill.——Dr. Evarts A. Graham, assistant professor of surgery at Rush Medical College, has located at Mason City, Iowa, and has been appointed chief surgeon to the Park Hospital.

INDIANA

New Hospital.—The board of commisioners of Sullivan county have voted to build a hospital in Sullivan.

State Society Meeting.—The Indiana State Medical Association met at the Claypool Hotel, Indianapolis, September 22-24, under the presidency of Dr. Frank B. Wynn, Indianapolis. The following officers were elected: Dr. George F. Keiper, Lafayette, president; Drs. Llon J. Willien, Terre Haute, Albert C. Chenoweth, Winchester, and Walter F. Carver, Albion, vice presidents; Dr. Charles N. Combs, Terre Haute, secretary (reelected) and treasurer. Dr. J. Rilus Eastman, Indianapolis and Dr. Albert E. Bulson, Jr., Fort Wayne, were elected delegates to the American Medical Association. Fort Wayne was selected as the next meeting place, the meeting to be held on the last Thursday and Friday in September, 1916.

Personal.—Dr. Cameron Chamberlin, Indianapolis, is reported to be in a critical condition in the Presbyterian Hospital, Chicago, as the result of a nervous collapse.——Dr. Thomas C. Stunkard, Terre Haute, fractured his right arm above the wrist, while cranking his automobile, September 12.——Dr. Edmond J. Beardsley, Alexandria, was painfully injured September 9, by the fall of an iron awning which inflicted a severe scalp wound.——Dr. Lamar R. Knepple, Kokomo, was operated on in Good Samaritan Hospital in that city for appendicitis, August 31 and is doing well.——Dr. John P. Franz, Indianapolis, was painfully injured in an automobile collision during the past week.——Dr. Harold O. Williams has been elected secretary of the Kendallville Board of Health in place of Dr. Albert G. Coyner, who had been secretary more than twenty years, but who died recently. Dr. Cyrus A. Gardener, Kendallville, has been named in place of Dr. Harold O. Williams on the board of health.

IOWA

Hospital for Cherokee.—At a public banquet held in Cherokee, September 10, it was decided to raise a fund of $50,000 for the erection of a hospital.

Nurses' Home for Hospital.—The Park Hospital, Mason City, has recently purchased for $15,000 a new building for a nurses' home adjoining the hospital.

Wishes to Be Medical Inspector.—Dr. Louis A. Thomas, Red Oak, formerly secretary of the State Board of Control, who has been conducting a health examination of schoolchildren of Red Oak for the last three years, is said to be a candidate for the office of medical inspector of public schools of Des Moines.

Anthrax.—On September 16 it was reported that the danger of the spread of anthrax among cattle from the focus on a farm north of Muscatine had been overcome. The stock had all been given a second dose of a preventive vaccine by Dr. C. J. Hackett, the veterinarian in charge of the situation. The disease had caused the death of a number of cattle on the farm, but it was not allowed to extend to other farms.

Smallpox.—The smallpox which had prevailed at Davenport for the previous ten months was believed to have been eradicated, but the discovery of a case in the Madison School, September 20, by Dr. George M. Middleton, city physician, has again rendered the situation uncertain. A large number of pupils were exposed and radical measures have been taken to prevent the spread of the disease. Vaccination is still being urged.

Case Against Clinton Surgeon Dismissed.—The case of Joseph Knox, a mail carrier of Morrison, Ill., against Dr. David S. Fairchild, Jr., Clinton, in which the plaintiff claimed damages amounting to about $30,000 on the allegation that the Clinton surgeon, who had operated on him for kidney disease, had left a gauze sponge in his body, was closed September 22, by this entry in the Clinton District Court docket: "The case of Knox vs. Fairchild, dismissed; judgment against plaintiff for costs." This entry justifies Dr. Fairchild's contention that the case was absolutely without merit.

Free Medical Service.—Dr. William S. Norton, Muscatine, physician of Muscatine county, has offered to conduct a free clinic on three days of each week for the benefit of the poor of the city. The clinics will be held between 9 and 10 on Monday, Wednesday and Friday mornings and will be open to all patients recommended by the City Welfare Association.——It is announced that free medical service will be at the disposal of the students of the State University, Iowa City, this year. Whenever a student becomes ill, he will be at liberty to visit the hospital or to call a university student, without expense.

Personal.—Dr. Wilton W. McCarthy, Des Moines, who suffered a fracture of the femur in an automobile accident near Ames, September 11, was operated on in Mercy Hospital, Des Moines, September 19.——Dr. Channing E. Dakin, Mason City, has been appointed head physician of the Modern Brotherhood of America, succeeding Dr. George E. Baudry, Atchison, Kan.——Dr. and Mrs. Henry Matthey, Davenport, sailed from Rotterdam for New York on the *Rotterdam*, September 8.——Drs. Fred W. Sallander, and Sidney Maldon, Iowa City, sailed from New York September 6 on the *Noordam*, for London, and expect to enter the military service.——Dr. Sidney G. Hands, Davenport, has been elected treasurer of Scott County Medical Society, succeeding Dr. Theo. W. Kemmerer, Davenport, resigned to accept the position of assistant professor of pathology in the University of Southern California, Los Angeles.

MARYLAND

Typhus in Baltimore.—A second case of typhus fever was reported from the Bayview Asylum, September 18. The patient, a white woman living in East Baltimore, was isolated.

New Laboratory.—Work has begun on the foundation for the five-story building of the Hunterian Laboratory connected with Johns Hopkins Medical School. The new building is located at the corner of Wolfe and Madison Streets, will be 50 by 100 feet, and will cost about $65,000.

Hunner Victor in Suit.—The suit of Mrs. Bertha Stephenson and her husband, Charles Stephenson of Ridgely, Caroline County, against Dr. Guy L. Hunner, Baltimore, to recover $30,000 damages for alleged negligence in the performance of a surgical operation on Mrs. Stephenson, was dismissed September 17, by Judge Soper in the Superior Court.

Hospital Force Organizes for Defense.—The guards and other employees of the Springfield State Hospital have decided to form a provisional battalion for national defense at Sykesville. About sixty of the men are anxious to take the military training and the superintendent has arranged with the Adjutant General of the state to have a sergeant of the State Militia instruct the men at Springfield on alternate Saturdays.

Personal.—Dr. James M. H. Rowland, Baltimore, has been made a member of the Board of Regents of the University of Maryland, to succeed the late Dr. David Street.——Dr. Fred P. Weltner has been selected to fill the vacancy on the medical staff of the Sheppard and Enoch Pratt Hospital, Baltimore, caused by the resignation of Dr. Burt J. Asper, who will practice in Asper, Pa.——Dr. Samuel J. Fort, Baltimore, has been appointed physician to the State Bureau of Statistics and Child Labor, succeeding Dr. John C. Travers, Baltimore.——Dr. William E. Moseley, Baltimore, was operated on at the Maryland General Hospital, September 16, and is reported to be improving.——Dr. Frederick C. Warring, Baltimore, who was operated on recently in the Maryland General Hospital, is reported to be convalescen ——Dr. John C. Pound, Baltimore, is reported to be ill with fever.——Dr. William B. Blanchard, chief of the resident staff of the Maryland General Hospital, has resigned.——Fire in the laboratory of Dr. Howard E. Ashbury, Baltimore, September 9, caused damage estimated at several thousand dollars.——Dr. John F. Spearman, formerly of Mercy Hospital, Baltimore, reports that he is on duty in a German line hospital and expects to return to New York in October.——Dr. J. McPherson Scott, Hagerstown, has been appointed chief surgeon of the local staff of the Western Maryland Railroad.——Dr. Herbert E. Zepp, Baltimore, charged with having failed to report five cases of typhoid fever to the Baltimore Health Department, was exonerated and the charge was dismissed as the cases were found to have been reported as required by law.

MINNESOTA

Sanatorium Site Selected.—A site has been chosen for the tuberculosis sanatorium for Roseau and Marshall counties at a point about 5 miles southwest of Holt.

New Hospital Opened.—The Physicians' Hospital, Thief River Falls, erected at a cost of $15,000, was formally opened August 31. The institution has accommodations for twenty-five patients and is provided with up-to-date equipment. The members of the staff are Drs. Herman W. Froehlich, Harvey G. Hieber, Francis H. Gambell, Oscar F. Mellby and Jesse E. Douglass.

Union of Health Bodies.—A movement for merger of the State Sanitary Conference and the Minnesota Public Health Association was begun September 2 at a meeting of the directors of the latter body at Millard Hall, University of Minnesota, at which resolutions expressing approval of the plan, were unanimously adopted. The merger of the two organizations cannot be effected until after January 1 next, on account of a provision in the charter of the conference.

MISSOURI

Physicians' Building.—Contracts have been let for the new physicians' and surgeons' building, three stories in height, to erected at Seventh and Francis streets, St. Joseph.

Hospital News.—A new staff of physicians has been appointed in the Kansas City General Hospital for the hospital and health board.——The Maywood Hospital, Sedalia, was transferred August 24 to the control of the Sisters of Charity of the Incarnate Word.——A meeting of the stockholders of the Southwest Hospital Association, Springfield, was held September 10, at which a proposition was submitted to increase the capital stock from $20,000 to $30,000.

Personal.—Dr. Leroi Beck, Kansas City, was seriously injured by the overturning of his automobile, September 4.——Dr. Charles R. Woodson, St. Joseph, entertained the Buchanan County Medical Society at his sanatorium, September 2.——Dr. Clarence A. Revelle, police surgeon of Kansas City, was cut in the face and hands and bruised in a collision between a motor car and a jitney bus, September 2.——Dr. Clarence D. Ussher, formerly of Kansas City, but at present a medical missionary in Van, Turkish Armenia, is reported to be seriously ill.

Plan to Eliminate School Infections.—Dr. Paul Paquin, health director of Kansas City, has a plan which if adopted he believes will eliminate the spread of infectious diseases due to school contact. It is a modification of the course pursued in many schools at present, but is more thorough and lays greater stress on frequent or constant inspections, etc. The plan provides for the examination of all pupils before admission; frequent examinations by nurses and physicians at school; the teaching of hygiene in every school; work by nurses in the homes; the creation of student sanitary commissions to aid the work. It is estimated that the cost in Kansas City would be about $25,000 a year. The school board is said to be favorable to the plan, provided the money can be obtained.

NEW JERSEY

Hudson County Bacteriologic Laboratory.—A county bacteriologic laboratory has been established in Jersey City under the direction of Dr. Von der Leit.

Typhoid Vaccination for Sailors.—Health Commissioner Joseph F. X. Stack, Hoboken, has administered antityphoid serum to the 2,500 sailors on the German steamers interned in Hoboken.

Bitten by a Dog.—John Kennell, health commissioner of Passaic and president of the Society for the Prevention of Cruelty to Animals was bitten by a dog that was thought to have rabies.

Old Health Officer Employee Dies.—Joseph C. Sayres, aged 70 years, a member and secretary of the Rutherford Board of Health for twenty-nine years, died at his home, September 16.

Health Officer Need Not Be Physician.—At the request of members of the Board of Health of Newark, the examination for health officer of that city, which was held September 23, was thrown open to candidates not practitioners of medicine.

Personal.—Dr. Fred M. Corwin has been reappointed medical inspector of the public schools of Bayonne.——Dr. Charles S. Pancoast, Camden, is said to have been presented with a decoration on account of distinguished service performed by him in Hungary.——Dr. Frederick C. Burt, who has served two terms as mayor of Hammonton, has refused to accept renomination.

NEW MEXICO

Personal.—Dr. Thomas J. Cummins has been appointed medical director of St. Joseph's Sanatorium, Silver City.

New Health Slogan.—The secretary of the Commercial Club of Albuquerque has originated a new slogan for that town which is as follows: "Albuquerque, N. M., the town where the sick get well and the well get prosperous."

State Society Meeting.—The thirty-fourth annual session of the New Mexico Medical Society was held in East Las Vegas, September 6 to 8, under the presidency of Dr. William T. Joyner, Roswell, the subject of whose annual address was "Medical Organization and Public Health." Albuquerque was selected as the place of meeting for next year and the following officers were elected: president, Dr. Evelyn F. Frisbie, Albuquerque; vice presidents, Drs. Clifford S. Losey, East Las Vegas; John W. Kinsinger, Roswell, and Arthur H. DeLong, Gallup; secretary, Dr. Robert E. McBride, Las Cruces (reelected); and treasurer, Dr. Frank E. Tull, Albuquerque (reelected).

NEW YORK

Hospital Remembered in Physician's Will.—According to the terms of the will of the late Dr. Joseph L. Hicks, Flushing, all his surgical instruments, and the books and pamphlets in his medical library, are bequeathed to the Flushing Hospital.

Health Officers Removed.—The State Commissioner of Health, Dr. Hermann M. Biggs, announced the removal of Dr. Emerick W. Crispell, Williamstown, health officer for the township of Amboy, and Dr. William B. Acker, health officer for the town and village of Hannibal. Dr. Biggs had accorded hearings to these gentlemen on the charges of incompetence and negligence which had been filed against them, but neither of the accused officers appeared to answer to the charges.

Personal.—Dr. Oliver W. H. Mitchell has been reinstated as city bacteriologist of Syracuse.——Dr. Howard L. Van Winkle, who has been in charge of the Syracuse Laboratory, has resigned as first assistant city bacteriologist.——Drs. William J. Books, New York City, and James N. Dunn, Schenectady, and six nurses have assumed charge of the medical inspection of the children in the city schools of Schenectady.——Dr. Ida C. Benner, for twenty years supervisor of the primary grades of the schools of the city of Buffalo, has resigned.——Dr. Loring T. Swaim, orthopedist of the Clifton Springs Sanatorium, has resigned and will practice in New York City.——Dr. William J. Thompson of the staff of the Central Islip Hospital has been appointed senior physician to the Danvers, Mass., State Hospital.

Mohansic Sewage Disposal Plan Opposed.—Some time since the Mohansic State Hospital secured the opinion of Dr. Hermann M. Biggs, State Commissioner of Health, that the temporary drainage of the affluent from the sewage disposal plant of the hospital into a lake from which a part of the water supply of New York City was obtained would not be objectionable. The matter was referred to the Department of Water Supply, Gas and Electricity of the City of New York which, after investigation, seriously opposed the plan. The committee then referred the matter to the Committee on Public Health of the New York Academy of Medicine. This committee also fails to concur with Dr. Biggs, giving as its reasons that there is a marked difference of opinion among sanitary experts whether the method of treatment which is proposed renders such sewage harmless and therefore they are not at all convinced that the proposition lacks danger even though it is only a temporary provision. They further state that although this plan of disposal might be safe under the present administration of the State Department of Health, there is no guarantee that in the future it might not be most unsafe through faulty administration and inefficient supervision. They suggest that as disposal of this sewage into the Hudson River would cost the state but $120,000, the State Department of Health should urge this expenditure as preventing all possible further pollution of the Croton water supply from this source.

New York City

Personal.—Dr. and Mrs. George S. Murray have sailed for Liverpool.——Dr. William P. Strain of Far Rockaway recently sustained a fracture of the forearm.——Dr. Charles F. Pabst, Brooklyn, saved a woman from drowning at Patchogue, N. Y., August 26.——Dr. Elizabeth J. Van Slyke, who has been serving with the American Red Cross at France and Belgium, arrived in New York on the *Santa Anna*, September 1.

Successful Control of Rabies.—The Department of Health announces that the measures adopted last year for the control of rabies in this city have been successful, largely through the ordinance requiring the muzzling of dogs. The number of cases of rabies found in animals examined in the laboratories of the department decreased from sixty-four during the second quarter of 1914 to fifteen during the corresponding period of this year. There was a reduction of 267 in the number of persons examined for dog bite and of 282 in the number of dogs examined for rabies.

Find Medical Care of Schoolchildren Inadequate.—The Bureau of Welfare of Schoolchildren of the New York Association for Improving the Condition of the Poor, of which William D. Straight is chairman, has issued a statement derived from the study of health department statistics, which indicates that 695,600 of the 925,000 schoolchildren of New York City, or 75.2 per cent. of all schoolchildren, are in need of medical attention for one or more of the physical defects common to children. Owing to the inadequacy of the staff of doctors assigned to school inspection and examination of children only 33 per cent. of the children are given a thorough physical examination each year. The statement points out that 167,577 children failed of promotion and assuming that this failure in a certain proportion of the children was due to the handicap imposed by one or more physical defects, the question is shown to have a serious financial side, since in addition to the amount expended by the health department it would cost the city $2,898,000 to reeducate this group of children who failed to advance.

NORTH CAROLINA

Third Antityphoid Campaign Opened.—The third antityphoid campaign to be inaugurated in North Carolina by the State Board of Health began in Craven and Warren counties, September 13. The county physician and a representative from the State Board of Health is in charge of the campaign in each county.

Examination Hours Restricted.—The State Board of Health has issued a notice that examinations for admission to the State Sanatorium for the Treatment of Tuberculosis, will be made only in the morning hours of the day, and patients are requested to communicate with the sanatorium and make appointments for such examinations.

Hospital Addition.—The addition to the Mission Hospital, Asheville, is almost completed and will be ready for occupancy by November 1. The addition is three stories and basement in height, fireproof and contains thirty-three rooms, of which thirty-one are to be utilized for patients. When the new building is in service, the hospital will have accommodations for forty-five private patients and thirty-six ward patients.

Bulletin for Teachers.—In connection with the State Department of Education, the North Carolina Board of Health is preparing to bring the subjects of health, disease prevention, and sanitation more closely to the attention of the public school teachers and public schoolchildren of the state. A bulletin is being prepared for the use of teachers which will contain the material for three-minute health talks, and may be used as a supplemental course in physiology, sanitation, and hygiene.

Registering Nurses and Cooks.—A number of cities and towns in the state have passed ordinances providing for the registering of washerwomen. The ordinance demands that they shall have certificates of good health and shall furnish sanitary premises and utensils for doing their work. In a *Bulletin of the State Board of Health* it is said that householders have protested that this ordinance is too narrow, and that it should include nurses and cooks, as they are even more important as disease-spreading factors. An instance is cited of one householder who reported that of three servants employed two were found to have tuberculosis and another a "worse disease." Each had succeeded in keeping the symptoms concealed for a time. The extension of protective ordinances to this class of help is advocated.

PENNSYLVANIA

Municipal Sanatorium Opened.—The new municipal tuberculosis sanatorium for Pittsburgh on the Leech farm, opposite Highland Park, is almost ready to receive patients. The institution has accommodation for 125 patients and several hundred applications for admission are already on file.

Hospital Notes.—Ground has been broken for the additional wing to the Braddock General Hospital to cost $80,000. When finished this will double the capacity of the hospital which now can accommodate seventy patients.——A new operating room, built and equipped at a cost of $40,000, was opened in the McKeesport Hospital, September 16.

New Cases of Typhoid at Danville.—Six new cases of typhoid were reported at Danville, September 22, bringing the total to sixty-nine. Five also have been reported in Mahoning township adjoining the borough, and six from Riverside. Two deaths were reported in the Danville State Hospital for the Insane, bringing the number up to eleven, but no new cases developed beyond the 133 already reported, which adds to the strength of the belief that the epidemic has been controlled through immunizing vaccination.

Personal.—Dr. Clinton T. Saylor, Rockwood, is reported to be seriously ill with appendicitis in the Memorial Hospital, Johnstown.——As the result of a civil service examination recently held in Illinois, to select a state psychologist, Dr. Harrison L. Harley, state college, headed the list and has taken up his duties at the Lincoln State School and Colony.——Dr. Thomas McC. Maxwell, Butler, was painfully injured in an automobile accident, September 16.——Dr. Jacob D. Liebermann, West Grove, is reported to be in a critical condition from septicemia.——Dr. Charles J. Hunt, Harrisburg, has been appointed a member of the staff of the Clifton Springs (N. Y.) Sanitarium.——Dr. James L. Yagle, New Freedom, was run over by his automobile, September 3, but was not seriously injured.——Dr. John J. Ott, Pleasant Valley, is reported to be seriously ill with heart disease at Applebauchville.——Dr. J. Frank Small, York, celebrated the twenty-fifth anniversary of his entrance into the practice of medicine, his retirement from practice and his fiftieth birthday, at his country home, south of York, by entertaining the York County Medical Society at dinner. Dr. Small was presented with a solid mahogany silver-headed cane, appropriately engraved.

State Society Elects Officers.—At the annual meeting of the Medical Society of the State of Pennsylvania held in Philadelphia, September 20-24, the following officers were elected: Dr. Charles A. E. Codman, Philadelphia, president; Drs. J. Torrance Rugh, Philadelphia; Edgar M. Green, Easton; W. Albert Nason, Roaring Spring, and Meyers W. Horner, Mt. Pleasant, vice presidents; Dr. Cyrus Lee Stevens, Athens, secretary (reelected); Dr. Clarence P. Franklin, Philadelphia, assistant secretary; Dr. George W. Wagoner, Johnstown, treasurer; Drs. Irwin J. Moyer, Pittsburgh; James Johnston, Bradford; John B. Lowman, Johnstown, and Jay B. F. Wyant, Kittanning, trustees and councilors; delegates to the American Medical Association, Drs. Americus R. Allen, Carlisle; William F. Bacon, York; Wilmer Krusen, Philadelphia; Charles C. Strickland, Erie, and Frederick L. Van Sickle, Olyphant; and alternates, Drs. Theodore B. Appel, Lancaster; Herbert B. Gibby, Pittston; George G. Harman, Huntingdon; Warren F. Klein, Lebanon; John A. Hawkins, Pittsburgh; Alice M. Seabrook, Philadelphia; Albert R. Matheny, Pittsburgh; William P. Walker, South Bethlehem; Robert B. Watson, Lock Haven, and Charles W. Youngman, Williamsport.

Philadelphia

Ground Broken for Hospital.—Ground has been broken for the erection of a three-story prison hospital for Moyamensing Prison, at the corner of Reed Street and Passyunk Avenue. It will be of granite, 36 by 43.5 feet, and will cost $18,000.

New Wards at the Polyclinic Hospital.—The Augusta Caroline Thorn Wards, presented to the Polyclinic Hospital by her daughter, Miss Mary Thorn, were opened at the hospital, September 22. The wards, which have accommodation for forty patients, cost $7,000. There are five rooms in all, designated as follows: women's surgical ward, women's medical ward, women's private ward, recovery ward, and the serious case ward.

To Raise Fund for the Children's Hospital.—Within a few days the board of managers of the Children's Hospital will announce the opening of a campaign to raise $500,000 to aid in completing the group of buildings for the site at Eighteenth and Bainbridge streets. One building is already finished and if the campaign is successful, plans for the main hospital building will be completed at once. Necessity for this work is emphasized by the fact that while there are in Philadelphia at the present time approximately 350,000 children less than 12 years old, the total hospital accommodation for such children is less than 900 beds.

Medical Institutions About Philadelphia.—Philadelphians will give a modern hospital to the State Masonic Home, Elizabeth, Pa. The building, for which architects are now preparing plans, is to be three stories high, of stone construction and 35 by 100 feet.——Title has been taken by the Orthopedic Hospital to the Parish House at the coroner of Seventeenth and Summer streets, from the Protestant Episcopal Church of St. Luke and the Epiphany for $40,000. The building will be used as a dispensary.

Personal.—Dr. Michael G. Wohl, pathologist to the Samaritan and Howard hospitals, has left Philadelphia to take charge of the laboratory of the Nicholas Senn Hospital, Omaha.——Dr. and Mrs. W. B. Dixon, Frankford, celebrated the sixty-fifth anniversary of their wedding, September 11.——Dr. Luther C. Peter has been elected associate professor of diseases of the eye in the Philadelphia Polyclinic.——Dr. J. William White returned home September 2 after two months of service in the American Ambulance, near Paris.——Dr. J. B. Frame has sailed for Persia as a medical missionary of the Presbyterian Board of Foreign Missions.——Dr. Malcolm C. Grow sailed from New York, September 12, on the steamship *Dvinsk* to serve in a Russian military hospital.

CANADA

A Doctor's Exciting Experiences.—Dr. W. V. Sargant has arrived home in Kingston, Ont., after a lively seven weeks. The government transport on which he went to England early in August was chased by a submarine, and he sailed for home as medical attendant on the S. S. *Hesperian*, which was torpedoed and sunk.

Toronto Physician Returns from Serbia.—Dr. James K. Mossman, Parry Sound, has returned from Serbia, suffering from septicemia contracted by cutting his finger during an operation. Before he went to Serbia 131 doctors in the whole empire out of 300 had succumbed to typhus fever. Dr. Mossman had charge of 300 patients and there were altogether over 4,000 patients with the disease in the town where he was stationed. There were not nearly enough doctors in that country to look after the wounded. A French commission was sent out in the spring which vaccinated all the people in the kingdom both civil and military against smallpox and cholera.

University News.—Queen's medical faculty is hoping the British War Office may see its way clear to allow Lieut.-Colonel Walter T. Connell, M.D., professor of bacteriology and public medicine, who is at present with Queen's Stationary Hospital at Cairo, Egypt, to return to Kingston for the work of the coming session. It has been found impossible to secure a competent supply to fill his position. Twelve of the third and fourth year medical students in France and in England are expected to return for the session's work——Nearly one third of the doctors on the medical faculty of the University of Toronto will be missed when the term opens on September 28. Of the staff of 197 professors and lecturers forty-three went to the front with the University Base Hospital. Dean Clarke states that the medical faculty will probably have as many students this year as last year in spite of the large numbers who have enlisted.

Hospital News.—Members of the different faculties of Laval University, Montreal, met last week in special convention, called by the special committee in charge of the scientific organization of the Laval University Stationary Hospital, and passed the following resolution: "We learn with pleasure of the initiative of the Faculty of Medicine in organizing the Laval Stationary Hospital."——Dr. James C. Connell, dean of the Medical Faculty of Queen's University, Kingston, says that the Egyptian authorities declare that Queen's Stationary Hospital, established at Cairo, Egypt, is the best equipped hospital that has arrived there from France or Britain. It is the only hospital there with a laboratory and an expert pathologist. There are

480 beds in the hospital.——The Ontario Military Hospital being established at Orpington, in the county of Kent, England, under the supervision of the Hon. Dr. Robert A. Pyne, Toronto, has grounds comprising 27½ acres. It has a large dwelling house capable of accommodating a considerable portion of the staff, and Dr. Pyne is proceeding with the erection of temporary buildings to house the hospital. The buildings will accommodate 1,040 patients as well as a number of assistants. They are being erected on lines approved by the British War Office and under the direction of an architect who has had wide experience in construction of that kind, having built several of the British war hospitals. The work will be pushed forward as rapidly as possible. The institution will be known as the Ontario Military Hospital, and Dr. Pyne is remaining in England for the present to personally oversee the erection and equipment of the hospital.

Personal.—Dr. Alfred K. Haywood, assistant superintendent of the Toronto General Hospital, who has been home on sick leave, leaves for his duties in Northern France, October 2.——Lieut.-Col. Ernest C. Ashton, M.D., Brantford, Ont., has been promoted to the rank of brigadier-general.——Dr. James P. Rankin, Stratford, Ont., has been successful in qualifying for the rank of lieutenant-colonel in the Canadian Army Medical Corps.——Dr. Arthur M. Fisher, Woodstock, N. B., and Dr. Lorne deC. MacIntosh, Hartland, N. B., who recently joined the R. A. M. C., have gone to Egypt.——Dr. William D. Sharpe, Brampton, Ont., has been appointed to the staff of a hospital in Serbia.——Dr. George H. Bowlby, Berlin, Ont., has left for overseas service.——Dr. Charles Valery, Edmonton, Alberta, has been appointed chief of the medical service of the fifty-ninth division of the French army.——Among Toronto physicians taking training in the provisional school of instruction for officers of the Army Medical Corps at Niagara-on-the-Lake are: Drs. Frederick A. Cleland, George D. Carleton, Hector C. Hall, B. P. Matthews, W. J. Naber, James M. McCormack, McKilgow, Robert W. Phillips, W. M. Robb, Harold P. Rogers, S. O. Rogers, F. G. Thompson, F. G. Wonbridge and C. R. Young. Other medical men taking this course are J. A. McCampbell, Waubashene, Ont.; Frederick A. Ross and W. A. Lewis, Barrie; George T. Bailey, Cochrane; W. J. Kirby, Englehart; H. H. Harrier, Coldwater; Herbert W. Armstrong, Fergus; D. M. Baker, Toronto; John P. Russells, Cobalt; Lyman C. Lauchand, Dundas; James R. McLean, Salt Ste. Marie; Thomas A. Gourley, Cayuga; F. J. Matthews, Brooklyn, N. Y.

GENERAL

Mississippi Valley Medical Association Meeting.—The forty-ninth annual meeting of the Mississippi Valley Medical Association will be held at the Phoenix Hotel, Lexington, Ky., October 19 to 21, under the presidency of Dr. Hugh Cabot, Boston. Dr. Carl Lewis Wheeler is chairman of the committee on arrangements.

Tuberculosis Week.—Philip Jacobs of New York, on behalf of the National Association for the Study and Prevention of Tuberculosis, announces that tuberculosis week has been arranged from December 6 to December 12. On December 8 a nation-wide plea is to be issued for every citizen of the United States to go to a physician to be examined for tuberculosis. December 10 is to be known as Children's Health Crusade Day.

Obstetricians and Gynecologists Elect Officers.—At the twenty-eighth annual meeting of the American Association of Obstetricians and Gynecologists held in Pittsburgh, September 14 to 16, the following officers were elected: president, Dr. Hugo O. Pantzer, Indianapolis; vice presidents, Drs. Gordon K. Dickinson, Jersey City, N. J., and O. G. Pfaff, Indianapolis; secretary, Dr. E. Gustav Zinke, Cincinnati (reelected); and treasurer, Dr. Herman E. Hayd, Buffalo. Indianapolis was selected as the place of meeting for 1916.

Prevention of Infant Mortality.—The sixth annual meeting of the American Association for Study and Prevention of Infant Mortality will be held in Philadelphia, November 10-12. The subjects to be discussed include Eugenics; Effect of the Economic Standing of the Family on Infant Mortality; Infant Welfare Nursing in Small Cities, Towns and Rural Districts; Institutional Mortality; Midwifery Conditions, and Treatment and Prevention of Respiratory Diseases. The session on Economic Aspects of Infant Welfare will be a joint one with the Philadelphia Medical Society, and will be held at the College of Physicians, November 11.

Health Experts Elect Officers.—At the close of the meeting of the American Public Health Association in Rochester, N. Y., September 10, the following officers were elected: president, Surg. John F. Anderson, U. S. P. H. S., Washington, D. C.; vice presidents, Drs. George W. Goler, Rochester, N. Y.; Charles J. C. O. Hastings, Toronto, Ontario, and Omer R. Gillett, Colorado Springs, Colo.; secretary, Prof. Selskar M. Gunn, Boston, and treasurer, Lee K. Frankel, New York City. Maj. Gen. William C. Gorgas, Surgeon-General, U. S. Army; Dr. C. Stephen Smith, New York City; Dr. Henry D. Holton, Battleboro, Vt., and Dr. Frederick Montizambert, director-general of public health of the Dominion of Canada, Ottawa, were elected honorary members.

Bequests and Donations.—The following bequests and donations have recently been announced:

Jewish Hospital, Philadelphia, $10,000 by the will of August B. Loeb.

Episcopal Hospital, Philadelphia, and Emergency Hospital, Easton, Pa., each $1,000 by the will of Elizabeth Bartlett.

Salem (Mass.) Hospital, $5,000 to maintain a child's free bed to be known as the Arthur Curwin Davis free bed and to provide an appropriation for James B. Curwin, first president of the hospital; and one third of the residue of the estate after the payment of bequests, to the Massachusetts General Hospital, Boston, by the will of Caroline E. Davis.

Masonic Home, Charlestown, Mass., $10,000; Home for Incurables, Boston, Boston Floating Hospital, and Industrial School for Crippled and Deformed Children, each $5,000 by the will of Isaac Eddy, Dorchester, Boston.

Cleveland Medical Library, a maintenance fund of $200,000 by the will of Dr. Dudley P. Allen. The fund is left in trust with the Cleveland Trust Company, the principal to remain intact and the net income is to be turned over to the Association for the next hundred years, or as much longer as the library is efficiently maintained.

To aid in the fight against tuberculosis in Dallas, Tex., a donation of $1,000 by P. P. Martinez.

New York Throat, Nose and Lung Hospital, and New York Association for the Blind, each $5,000 by the will of Francis Finch Robins.

Harvey Society.—The program of the eleventh lecture course of the Harvey Society has just been published. The lectures will be given on Saturday evenings at 8:30, under the patronage of the New York Academy of Medicine, at its building at 17 West Forty-Third Street, New York. The program is as follows:

October 16.—Prof. C. W. Stiles, Hygienic Laboratory, Washington, D. C. "Recent Studies on Schoolchildren, with Special Reference to Hookworm Disease and Sanitation."

November 6.—Prof. A. J. Carlson, University of Chicago. "Recent Contributions to the Physiology of the Stomach."

November 27.—Dr. Eugene F. Du Bois, Cornell University. "The Respiration Calorimeter in Clinical Medicine."

December 18.—Prof. Florence R. Sabin, Johns Hopkins University. "The Method of Growth of the Lymphatic System."

January 15.—Dr. Donald D. Van Slyke, The Rockefeller Institute for Medical Research. "The Present Significance of the Amino Acids in Physiology and Pathology."

February 5.—Dr. Hideyo Noguchi, The Rockefeller Institute for Medical Research. "Spirochetes."

February 26.—Prof. Warfield T. Longcope, Columbia University. "The Susceptibility of Man to Foreign Proteins."

March 11.—Prof. Henry A. Christian, Harvard University. "Some Phases of the Nephritis Problem."

March 25.—Dr. R. T. Woodyatt, University of Chicago. "A Conception of Diabetes."

April 8.—Prof. Stanley R. Benedict, Cornell University. "Uric Acid in Its Relations to Metabolism."

April 29.—Prof. William H. Welch, Johns Hopkins University. "Medical Education in the United States."

The Plague Situation in New Orleans.—After a lapse of nearly a year a case of human plague occurred in the city of New Orleans, August 27. This case was confirmed as true bubonic plague on September 8. The epidemiologic investigations as to the exact source of the infection have not yet been completed but it is believed that it was probably received in the city of New Orleans. The occurrence of this case demonstrates the difficulties surrounding the eradication of the disease and indicate that had it not been for the active cooperative efforts of the United States Public Health Service and of the departments of health of the state of Louisiana and the city of New Orleans, the outbreak would have reached greater proportions and would have been longer continued. It also points out to other cities the necessity for ridding themselves of the rodent carriers of the disease and of thoroughly rat proofing all of their buildings. No fear is felt that this case will be followed by an outbreak. Officers and men of the Public Health Service, well trained in the control of the disease, are on the ground and with the health authorities of the city of New Orleans are taking every precaution to prevent the spread of the disease from the city and within it. During the three months from July 17 to September 18, the United States Public Health Service, in its work against bubonic plague in New Orleans, fumigated 118 vessels with sulphur, 144 with carbon monoxid and 15 with hydrocyanic acid gas; and issued 345 clean bills of health and 54 foul bills of health. In the department of field operations 56,233 rats were trapped, 101,226 premises were inspected and 7,281 buildings were rat proofed. The department of laboratory operations received 7,281 specimens of mus rattus; 13,988 of mus Norvegicus; 1,090 of mus Alexandrinus; 38,915 of mus musculus; 466 wood rats, 308 musk rats and 842 putrid rats. In all, 56,160 rats were received at the laboratory. Of these, 18,605 were examined, 169 were found suspicious and in 7 rats the diagnosis of plague was confirmed. The confirmed rodent cases were as follows: No. 245, captured at 617 St. Marys Street, July 7, diagnosis confirmed July 14, premises treated by intensive trapping, premises vacated and demolished and rat proofing initiated: No. 246, captured at Galves and Erato streets, July 13, diagnosis confirmed July 20, and premises treated with intensive trapping in the neighborhood and on the Galves dump and pushing forward of the rat-proofing operations; No. 247, captured at 536 S. Roman Street, August 1, diagnosis confirmed August 8, premises treated by intensive trapping, destruction of rat harbors, spraying of the premises with pulecide and the completion of rat proofing; No. 248, captured at 2503 Howard Street, August 17, diagnosis confirmed August 25, and the premises treated by intensive trapping, destruction of rat harbors, premises sprayed with pulecide and rat proofing expedited; No. 249, captured at Harmony Street Wharf, August 19, diagnosis confirmed September 2, and premises treated by intensive trapping; No. 250, captured at 1423 Joseph Street, September 6, diagnosis confirmed September 12, premises treated by summary destruction of rat harbors, spraying of pulecide in the vicinity, intensive trapping and rat proofing, and No. 251, captured at 837 S. Fulton Street, September 9, diagnosis confirmed September 14, premises treated by intensive trapping, fumigation by cyanid gas and rat proofing. During the week ended July 24, one suspicious human case was inspected and another during the week ended August 28, and one human plague case was discovered as reported above. Since the initiation of the work against plague in New Orleans, 44,938 buildings have been rat proofed, and 442,497 rodents have been captured, of which 286,087 were examined. Rodent plague was found in 4 cases in mus musculus, in 17 cases in mus rattus, in 8 cases in mus Alexandrinus, and in 222 cases in mus Norvegicus.

Annual Report of Rockefeller Foundation.—The first part of the annual report of the Rockefeller Foundation, covering the period to the end of 1914, deals with the activities of the international health commission. This commission was established June 27, 1913. Mr. Wickliffe Rose, administrative secretary of the Rockefeller Sanitary Commission for the Eradication of Hookworm Disease, was appointed director-general; Dr. John A. Ferrell, assistant director-general, the president and secretary of the organization serving ex-officio as chairman and recording secretary, respectively. The commission had assigned to it, two tasks: to extend to other countries the work of eradicating hookworm disease, and to follow up as far as practicable, the treatment and cure of this disease, together with the establishment of agencies for the promotion of public sanitation and the spread of the knowledge of scientific medicine. The hookworm infection includes practically all countries within the zone from 36 North to 30 South latitude and about 900,000,000 of the 1,600,000,000 inhabitants of the globe live in countries where the infection is prevalent. In the southern states, 39 per cent. of the 548,992 rural children microscopically examined were found to be infected; 90 per cent. of the population of the United States of Colombia, living between sea level and a latitude of 3,000 feet are infected; 50 per cent. of the population of British Guiana is infected; 90 per cent. of the population of Dutch Guiana; 50 per cent. of the laboring population of Egypt; 50 per cent. of the coolies in Natal and 90 per cent. among the plantation laborers in Ceylon are victims of the disease, and in some parts of India and among the coolies on the estates in Malaysia and Fiji which import their laborers from India there is a large percentage of infection. The southern two-thirds of the Chinese empire is infected, the infection of the farm population in the Yangtse Valley running as high as 76 per cent. The relief and control of the disease involve first a survey to determine the geographic distribution and approximate degree of infection; the microscopic inspection of the people and the cure of the infection, and the setting in operation and making effective such sanitary measures as will stop soil pollution. During the first year of the existence of the commission, trips for preliminary examination and conference were made to England, the British West Indies, Egypt and the British dependencies in the Far East and to Central America. As a consequence of these visits, work has begun in British Guiana, Antigua, Trinidad, St. Lucia, Grenada, Egypt, Ceylon, the Malay states, Panama, Nicaragua, Costa Rica and Guatemala. In addition to this work in foreign countries, the commission has also undertaken to complete the program of the Rockefeller Sanitary Commission for the eradication of uncinariasis in the southern states. The methods pursued include work under authority and direction of the government which was begun on a small scale; the treatment of those found infected; a survey of the geographic distribution of the infection; preventive measures and education of the people, the whole being designed as an object lesson in the treatment of disease, demonstrating that as one disease has been conquered others may be.

FOREIGN

Death of Professor Ewald.—Carl Anton Ewald's name fills a prominent place in textbooks on diseases of the digestive tract, as he has contributed much to the diagnosis, differentiation and management of stomach affections. He was born at Berlin, Oct. 30, 1845, and had thus nearly completed his seventieth year. He was one of the two editors of the *Berliner klinische Wochenschrift* until he resigned this task in 1907. He was the successor of Senator in the internal medicine service at the Augusta Hospital, and has served constantly since 1886. Besides numerous works on the pathology of the digestive organs, the Ewald-Boas test breakfast, the Ewald test meal, his stomach tube, and the Ewald-Boas method of expelling the gastric contents through the stomach tube, his name is connected with Sievers' in a clinical test of the motor functioning of the stomach. Before his last long illness, Ewald had taken an active part in sanitary organization, especially in establishing seaside homes for weakly children, and was appointed regular Honorarprofessor in 1908. He has been privy councilor, Geh. Med.-Rat, since 1898. The cable announces his death September 25.

WAR NOTES

Medical and Surgical Exports Increased by War.—The manufacture, in the United States, of drugs, surgical instruments and other medical appliances represented—as long ago as 1909—an approximate aggregate production of $165,000,000. Ordinarily, the total export of this material averages 10 per cent. The following table taken from *Commerce Reports*, July 19, illustrates the rapid growth of export trade in such materials in a single year, obviously due to the international conflict raging in Europe:

Articles	Year ending June 30	
	1914	1915
Surgical appliances	$ 1,289,000	$ 4,500,000
Medical and surgical instruments	206,000	300,000
Dental goods	2,679,000	1,274,000
Patent or proprietary medicines	6,722,000	7,200,000
Miscellaneous drugs, chiefly disinfectants	9,020,000	22,500,000
Total	$19,916,000	$35,774,000

Aid for Belgian Physicians.—The report of the treasurer of the committee of American physicians for the aid of the Belgian profession, for the week ended Sept. 24, 1915, lists the following contributions:

Norfolk County Medical Society, Norfolk, Va.		$ 28.00
Carroll County Medical Society, Wolfeboro, N. H.		10.00
Muscogee County Medical Society, Columbus, Ga.		14.00
Receipts for the week ending September 25		$ 52.00
Previously reported receipts		7,814.84
Total receipts		$7,866.84
Previously reported disbursements:		
1,625 standard boxes of food at $2.20	$3,575.00	
1,274 standard boxes of food at 2.30	2,930.20	
353 standard boxes of food at 2.28	804.84	
Total disbursements		7,310.04
Balance		$ 556.80

LONDON LETTER

London, Sept. 17, 1915.

The War

THE DEARTH OF PHYSICIANS: NEW SCHEME FOR THE ARMY

The problem of the medical student and the need for more physicians continues to cause anxiety. The director-general of the Army Medical Corps has announced that to outfit the new armies and to supply reinforcements for six months it was estimated that at least 2,500 more physicians of military age would be required. It has been found necessary to bring physicians from Canada, Australia and New Zealand. The hospitals have been in difficulties for some time. Recently the chairman of the British Hospitals Association met Sir Alfred Keogh, director-general of the Army Medical Corps, on the subject. Sir Alfred agreed to extend to all hospitals connected with medical schools the arrangements under which the resident staffs of hospitals are granted honorary commissions in the Army Medical Corps, but he could not extend the operation of the scheme to other hospitals. The following are the details: 1. The scheme is applicable only to hospitals connected with recognized teaching schools (not postgraduate schools). 2. All candidates for commissions must be registered physicians. 3. They must be physically fit for general service. 4. They shall be called on to take general service with the Royal Army Medical Corps after three months' residence, and shall be liable to be called up for service before the expiration of that period, if required, on forty-eight hours' notice. 5. So far as practicable, not more than one third of the number of residents will be called up on forty-eight hours' notice at one time. 6. Each candidate shall, on being approved for a temporary honorary commission, receive a grant of $100 as an allowance for the purchase of uniform. This is part of the grant of $150 issuable on taking general service. 7. No undertaking can be entered into that any residents called up for service will be replaced by the War Office. 8. Applications for temporary commissions should be made to the War Office by the hospital authorities concerned, who will vouch for the candidates whose names they submit. 9. The authorities of any hospital who wish to avail themselves of this scheme should inform the War Office of the number of beds maintained in the institution, and the number of residents employed. The effect of this scheme will be that hospitals will to some extent be secured against losing resident officers, and young physicians going to the front will have some special training before they go.

WOMEN PHYSICIANS

Mr. F. D. Acland, speaking at a meeting in support of the London School of Medicine for Women, said the supply of male physicians was not sufficient to meet the demands of the present day, and would be quite inadequate in the future. There were hospitals in London speaking of closing, not because of lack of patients, but because of lack of physicians. They were now beginning to realize the value of women physicians, and it was a pity they had not done so earlier. This war was teaching the nation the great sphere which medicine now occupied in national welfare. We were learning in a terrible way the cheapness of life and at the same time realizing the value of human life. Sir Berkeley Moynihan said that if five years ago the cost of one day's war at the present rate had been devoted to research work the scourge of tuberculosis would now be hastening to its conclusion, and we should probably have been free from cancer. Writing on the decrease in the number of male medical students and the shortage of physicians which must follow, the *Lancet* says that we must look to the increased entry of women into the medical ranks to meet the situation thus created. "In much of the glut of work at home women are playing their part, and the country has observed with pleasure that the war has given to them a fresh impetus towards the study of medicine. Apart from general practice there are certain well-defined directions where women will find congenial occupation, assured incomes, and opportunities for the recognition of their scientific work." Among these are the superintendence of children's clinics, the inspection of child life, the treatment of diseases of children and women, and practice overseas, particularly in India.

WOMEN DISPENSERS

The War Office is now engaging women dispensers for the military hospitals. The qualifications required are membership in the Pharmaceutical Society, or the assistant's diploma of the Apothecaries' Society. The latter is the qualification usually held by women, who are being engaged only for the duration of the war, in order to permit the male assistants to be sent abroad. The pay is $1.46 per day, Sundays included. In certain county districts allowance and rations are given. The hours are from 9 a. m. to 5 p. m. The women dispensers have given satisfaction, and the War Office has increased the number employed.

Irish Vital Statistics

The Annual Report of the Registrar-General for Ireland has just been issued. The birth rate was low—22.6 per thousand of the population. The marriage rate was 5.41 per thousand—the highest since 1867. The death rate was 16.3—the lowest recorded in Ireland since 1868. The emigration rate was 4.6, much below that for any year since emigration returns were first compiled in 1851. The estimated population in the middle of 1914 showed an increase of 2,386 on the estimate for the middle of 1913. The births during the year 1914 amounted to 98,806, or 22.6 per thousand, which is 0.7 below the average rate for the ten years 1904-1913. Old age, as usual, occupies first place in the causes of death, being credited with 11,565 deaths; tuberculosis comes next with 9,089; and, then, in order, heart diseases, bronchitis, pneumonia, cancer. The tuberculosis death rate shows marked decline in recent years. From 1864 to 1878 it varied between 2.4 and 2.6 per thousand living. From 1879 to 1908 it varied between 2.6 and 2.9. From 1904 the decline has been fairly steady, the rate in the successive years being: 2.88; 2.70; 2.67; 2.66; 2.58; 2.41; 2.28; 2.20; 2.15; 2.14, and 2.07. But the rate is still much higher than that for England, which is 1.4.

BERLIN LETTER

Berlin, Aug. 31, 1915.

Personal

Professor Friedberger, division chief of the pharmacologic institute in Berlin, has been appointed to succeed Professor Römer as ordinary professor of hygiene at Greifswald. Friedberger has made some very commendable researches in immunology.

Professor Gros of Leipzig has been appointed ordinary professor of pharmacology in Halle to succeed the late Professor Harnack.

A recently deceased cleric left the Berlin Institute for Cancer Research an endowment of 300,000 marks ($75,000).

The War

The exchange of severely wounded German and English prisoners is no longer being made. Germany and Russia are now making such an exchange. Provision is also being made to intern sick and convalescing prisoners of various nationalities in Switzerland. The different warring nations have given their consent to such an arrangement.

Although the number of Russian prisoners now in the hands of the Germans and Austrians is astoundingly large, still these two nations apparently are well prepared to make provision for them. Since May 2 no less than 1,100,000 Russians have been taken prisoners. At Braunau in Bohemia a prison camp is being constructed to take care of 100,000 prisoners, a number equaling the population of a large city, and yet the very best care is being given these men, as any American can convince himself by visiting these camps. Notwithstanding the fact that a large number of these Russian prisoners are brought to the prison camp in a most unhygienic condition and frequently suffering from some infectious disease, the care given them in the camp is such that the morbidity rate among the prisoners is remarkably low. Typhus is the disease met with most frequently, the next in order being cholera, typhoid, dysentery and smallpox.

As may be expected, such a large number of prisoners must have a considerable guard. Inasmuch as death and imprisonment must also be reckoned with among German soldiers, it is not possible to detail to the prison camp soldiers who are physically fit for duty at the front; hence, they have detailed to such duty the men who ordinarily were mustered out of service or rejected for service because of physical unfitness. This, of course, does not mean that cripples are detailed for this service, but men who ordinarily could be sent to the front in time of need and yet would not be considered absolutely fit for such duty. Notwithstanding this fact, it is rather remarkable to note how well these soldiers stand up under the strain of their duty. In fact, nearly all show a great improvement in health. A remarkable case in point is that of a man of 45 who, in 1897, entered a hospital because of an extensive left-sided empyema. A rib resection was done, but healing did not take place. Tubercle bacilli were not found. The surgeon performed a thoracoplasty, resecting five ribs, from the fourth to the eighth, removing all of the thickened pleura. The collapsed lung soon expanded again, and later an extensive plastic operation was performed. One-half of the left scapula was removed because the posterior rib stumps had become united to it. Convalescence was complicated by an acute nephritis and a very severe erysipelas. After two years the man was discharged as well. He was in fit condition for work and opened a window-cleaning establishment. When war was declared, his three sons went to the front and he volunteered for service. The military surgeon who examined him declared him unfit for duty because one-third of the left side of his thorax was missing. Thereon the man sought permission to enlist from the emperor himself and the request was granted. He was assigned to a transport as driver of a team, and in that capacity served throughout the entire campaign in France and without any personal inconvenience. Recently he was kicked in the right chest by a horse, and in consequence developed a hemoptysis. He was sent home on furlough. This case is one of great interest because it demonstrates that even a very extensive change in the thorax may permit of most unusual exertions and service.

PARIS LETTER

Paris, Sept. 9, 1915.

The War

THE PRACTICE OF SURGERY IN THE TERRITORIAL HOSPITALS

Experience has shown the disadvantages of leaving the initiative in surgical operations to physicians who are unfamiliar with the practice of military surgery, especially in certain unimportant hospitals. In some such cases, ill advised or useless operations, which would not have been performed in ordinary times without the assistance of a professional surgeon, have been performed to the detriment of the patients. To obviate these serious disadvantages, the minister of war has decided that all general surgical operations shall be performed exclusively by designated professional surgeons in each region after technical advice from the "head surgeons of sectors." The administration of the medical service has divided each territorial region (which represents a zone occupied in times of peace by an army corps) into three or four sectors corresponding to the military subdivisions of the region, and at the head of each of these sectors it has placed a head surgeon, who is to be in absolute control from the technical point of view, irrespective of all questions of rank.

These head surgeons of sectors are to fulfil two functions: 1. As operative surgeons each is to direct a surgical service in the place of his residence; he is to operate, moreover, after having consulted with the medical heads of the respective hospitals, in other establishments on patients who appear to him to need his personal attention. 2. As consulting surgeon, he is to visit the various establishments in his sector once every two weeks, first advising the medical heads of his coming; he is to give the physicians practicing there the necessary technical advice while refraining from becoming involved in questions of administration. In short, the head surgeon of a sector is at once operator, technical inspector and consulting surgeon.

While the head surgeons of sectors are to undertake the important operations within their respective territory, it is evident that they cannot perform all the operations. They must have surgical collaborators. The assistant secretary of state for the medical service has therefore directed the regional director to designate in all the important centers, after consulting with the head surgeon of the sector, one or several *chirurgiens de Place,* charged exclusively with the ordinary run of the surgery of the locality and of the neighboring hospitals, as well as with the urgent operations. These *chirurgiens de Place* are to be chosen from among the professional surgeons. They alone are to operate in the hospitals of that center and the environs.

The unimportant hospital centers are to receive only the slightly wounded patients, on the road to recovery and requiring only simple dressings. In case of an urgent operation on a patient in a hospital having no designated surgeon attached to its staff, the physician at the head of the hospital will telephone or telegraph to the head surgeon of the sector or of the nearest surgical center.

These rules apply only to major surgery (operations on the splanchnic cavities, resections, amputations, explorations for deeply situated projectiles). Minor surgical operations (the opening of abscesses and the extraction of superficial and easily accessible projectiles from the limbs) may be entrusted to the initiative of the physicians in charge of the cases, under the control of the *chirurgiens de Place.* The head surgeons of sectors are to make monthly reports on their tours of inspection and the technical functioning of their service, their residence and the territory within their jurisdiction. These documents are to be sent each month to the war department and to all the regional authorities.

PRISONERS OF WAR UNABLE TO ENDURE PRISON CAMPS TO BE PLACED IN SWISS HOSPITALS

It is well known that in the present war Switzerland has played an important humanitarian rôle, acting as intermediary in searching for prisoners, exchanging seriously wounded prisoners between France and Germany, etc. Switzerland is now about to undertake a new mission of trust, that of the hospital care of a certain number of prisoners of the various belligerent countries. These are to be patients who are not in a sufficiently serious condition to be returned to their own country, but who suffer particularly from the life in the prison camps. The first class taken care of there will probably be the tuberculous, who will be distributed among the principal climatic health resorts of Switzerland—Leysin, Montana, Davos, Arosa, etc. The prisoners are to be allowed a certain degree of liberty which is necessary for the reestablishment of their health. It is important, however, that they be not allowed to make use of this liberty to return home. It is probable that an agreement to this effect will be made not only by the prisoners themselves but also by the governments of their respective countries. Thereby surveillance will be much facilitated and the patients will be able to enjoy a certain degree of independence without entailing any abuses from which Switzerland would have to suffer.

THE HOSPITAL CARE OF PATIENTS WITH FISTULAS CAUSED BY WOUNDS OF WAR

The assistant secretary of war for the medical service has received a report of the presence in certain hospitals of a rather large number of soldiers almost cured of their wounds but still affected with fistulous openings caused by the presence of fragments of bone or of foreign bodies for which no active treatment has been undertaken. These patients ordinarily drag out a protracted stay in the unimportant hospitals, where it is not possible to undertake the surgical cure of these traumatic sequelae. The assistant secretary has therefore given instructions that all such patients who have been placed in hospitals where there is no surgical service shall be removed to hospitals having the necessary staff and equipment to operate for the speedy cure of such cases.

THE "DARDANELLES STAMP"

The Société française de Secours aux Blessés Militaires has contributed toward the conversion of the *Charles Roux,* a transatlantic liner, into a floating hospital. The society has furnished the boat with 300 beds and important hospital equipment. It has entirely at its own expense chartered another boat, the *Saint-François-d'Assise,* which is about to set out for the Dardanelles. The society has also sent out thirty nurses, some of whom are to work on board of the *Charles Roux,* while others are to be assigned to the ambulance units already established on the island of Lemnos. This work has imposed heavy expenses on the society. In order to meet these expenses, it has just issued a new five cent postage stamp called the Dardanelles stamp. This stamp shows an ambulance unit composed of several tents under the shadow of the French flag and the Red Cross standard; a nurse of the society is caring for a wounded soldier. This stamp is sold in books of twenty. On the cover of each book is a colored picture representing the *Charles Roux,* whose white hull is barred with a broad red stripe; at the masthead flutters the French flag and the flag of the Red Cross.

Accident to Professor Hayem

Dr. Hayem, formerly professor at the Faculté de médecine de Paris, has just been injured in an automobile accident which occurred in the outskirts of Chambéry.

Marriages

Clarence Searle Ketcham, M.D., Washington, D. C., to Miss Elizabeth Weed Rogers, at Huntington, L. I., N. Y., September 11.

John H. Nugent, M.D., Southampton, L. I., N. Y., to Miss Marie W. Moffitt of Center Moriches, L. I., N. Y., September 16.

Elmer Harrison Ormsby, M.D., Amsterdam, N. Y., to Miss Muriel Eloise Blackwood, of Huntingdon, Que., September 15.

Orel A. Welsh, M.D., Oregon City, Ore., to Miss Grace Wolcott of San Francisco, in Santa Cruz, Calif., September 11.

P. A. Surg. Ernest Oliver Joseph Eytinge, U. S. N., to Miss Marion Brooks, at Mare Island, Calif., September 11.

Henry Kleinschmidt, M.D., Oshkosh, Wis., to Miss Ethel Morris, of Farmington, Mich., in Detroit, September 1.

John Andrews Evert, M.D., Brainerd, Minn., to Miss Pearl A. Nash of Pipestone, Minn., about August 28.

Walter William Lowell, M.D., Brooklyn, to Miss Alice White of Brinsville, Ont., in Brooklyn, September 15.

Leslie Hall Redelings, M.D., Rochester, Minn., to Miss Gertrude Abbott of Plainfield, N. J., September 8.

Walton Evermont Muns, M.D., Columbia, Mo., to Miss Betty Hawkins, of New York City, September 6.

Thaddeus Hall Green, M.D., Bascom, Fla., to Miss Anna Lucia D'Antoni of Natchez, Miss., September 1.

Albert William Crews, M.D., Thurmond, W. Va., to Miss Pauline Riffe of Greenfield, Ind., September 16.

Ebenezer Ross Faulkner, M.D., to Miss Julia Whiton Little, both of New York City, September 11.

Clarence Vernon Smith, M.D., Tipton, Ind., to Christine Lukas, M.D., of Evanston, Ill., September 8.

Thomas Webster Edgar, M.D., to Miss Arleine E. Lamprey, both of New York City, September 7.

P. A. Surg. Emil Krulish, U. S. P. H. S., to Miss Sarah Sydnor, at Pasadena, Calif., August 30.

Deaths

Austin Flint, M.D. Jefferson Medical College, 1857; aged 79; died at his home in New York City, September 22, from cerebral hemorrhage. Dr. Flint was born in Northampton, Mass., March 28, 1836, the son of Dr. Austin Flint and Anne Skillings. He began his medical studies in the University of Louisville and after two years went to Philadelphia, where the degree of M.D. was given him by Jefferson Medical College in 1857. He practiced in Buffalo for two years, and was professor of physiology in the University of Buffalo. In 1859 he moved to New York City and became associated with the New York Medical College as professor of physiology. He then served in a similar capacity in the New Orleans School of Medicine for a year. At the outbreak of the Civil War Dr. Flint was appointed an Acting Assistant Surgeon in the Army and served for three years in this capacity in the General Hospital, New York City. He was one of the founders and for thirty-seven years was professor of physiology in Bellevue Hospital Medical College. During six years of this time he also filled the chair of physiology in Long Island Hospital College, Brooklyn. He associated himself with Cornell University Medical College in 1898 and was professor and professor emeritus from that time until his death.

He was a Fellow of the American Medical Association, an honorary member of the New York Academy of Medicine, a member of the Association of Military Surgeons of the United States and of many other learned societies. He was given the degree of LL.D. in 1885 and that of A.M. in 1894 by Princeton University and was decorated with the Third Class Order of Bolivar by the government of Venezuela in 1891. Dr. Flint had been visiting physician since 1869, consulting physician and visiting physician to the Insane Pavilion of Bellevue Hospital since 1896; was consulting physician to the Bellevue Hospital Dispensary for nearly fifty years, and from 1874 to 1878, he served as surgeon-general of the state of New York.

Dr. Flint was a prolific writer and his encyclopedic work on the Physiology of Man, in five volumes, has gone through two editions; his treatise on Chemical Examination of the Urine in Disease, is now in its sixth edition, and his Text Book of Human Physiology has required four editions up to the present time. He was also the author of other treatises and of many monographs and articles, chiefly on the subject of physiology, in which he specialized, and on medical biography and history.

Benjamin Lindsay Coleman, M.D. Bellevue Hospital Medical College, 1871; aged 68; a member and formerly vice president of the Kentucky State Medical Association; once president of the Fayette County Medical Society; member of the Mississippi Valley Medical Association; physician to the Good Samaritan Hospital, Lexington, Ky.; for many years curator of Transylvania University and a member of the Board of Trustees of Hamilton College; died at his home in Lexington, Ky., September 14, from cerebral hemorrhage.

Lorne Benjamin Graham, M.D. University of Toronto, Ont., 1907; formerly of Pacific Grove, Calif.; a member of the Medical Society of the State of California; who offered his services to the British Government at the outbreak of the war and was stationed at Eastbourne, England, as supervisor of Red Cross work and later was transferred to the Dardanelles; was killed in the Aegean Sea, August 17, when the transport on which he was proceeding to his new post of duty was sunk by a German submarine.

William F. Muhlenberg, M.D. University of Pennsylvania, Philadelphia, 1872; aged 62; a Fellow of the American Medical Association; formerly president of the Berks County, Pa., Medical Society; one of the founders and a member of the Board of Managers of the Reading Hospital; president of the Pennsylvania German Society; for more than thirty years surgeon to the Schuylkill Valley Railroad; died at his home in Reading, Pa., August 25, from myocarditis.

Emil Ernest Guenther, M.D. New York University, New York City, 1877; aged 61; a member of the Medical Society of New Jersey and a practitioner of Newark; formerly coroner of Essex County, N. J.; visiting surgeon to St. Michael's and St. Barnabas' hospitals, and a member of the staff of the German Hospital, Newark, N. J.; for many years a trustee of the Newark City Home; died at his summer home in Mountainview, N. J., September 12, from heart disease.

Chester Emory Coulter, M.D. University of Michigan, Ann Arbor, 1883; aged 60; for twenty-six years a practitioner of Ogden, Utah; a member of the staff of the Dee Hospital for many years; at one time city physician and a member of the Board of Education; died at his home in Ogden, September 12, from nephritis. The Weber County Medical Association attended the funeral service in a body.

P. Van Benschoten Fowler, M.D. Medico-Chirurgical College of Philadelphia, 1897; aged 49; a Fellow of the American Medical Association; for two terms secretary of the Suffolk County Medical Society; a member of the staff of the Babylon, L. I., Hospital, and of the school board of Centre Moriches, L. I.; died in Brentwood, L. I., September 14, from carcinoma of the stomach.

Susan LaFlesche Picotte, M.D. Woman's Medical College of Pennsylvania, Philadelphia, 1889; aged 49; a Fellow of the American Medical Association; for many years prominent as a medical missionary among the Indians of Nebraska and adjoining states; daughter of Chief Joseph, the last great chief of the Omaha tribe; died at her home in Walthill, Neb., September 18.

Charles R. Newton, M.D. University of Pennsylvania, Philadelphia, 1893; aged 58; of Nicholson, Pa.; a Fellow of the American Medical Association; physician in charge of the hospital maintained by the Delaware, Lackawanna and Western Railroad, for its workmen on the Tunkhannock bridge; died September 12, in Bellevue Hospital, New York City.

James Clinton Moore, M.D. University of Nashville, Tenn., 1900; aged 47; a member of the Medical Association of the State of Alabama; for several years a member of the Board of Education of Anniston and one of the prime movers in the building of St. Luke's Hospital; died at his home in Anniston, Ala., September 13, from heart disease.

Robert Gamaliel Cornwell, M.D. Long Island College Hospital, Brooklyn, 1875; aged 62; a member of the Medical Society of the State of New York; once health officer of Riverhead; jail physician for five years and for the last three years coroner of Suffolk County; died at his home in Riverhead, N. Y., September 16, from heart disease.

Charles Lee Crawford, M.D. St. Louis College of Physicians and Surgeons, 1893; aged 52; a Fellow of the American Medical Association; formerly of Vevay, Ind.; but since 1910 a resident of Carlisle, Ark., was shot and instantly killed September 12, near Carlisle, by a negro whom he was attempting to arrest for murder.

Abijah J. Miles, M.D. Medical College of Ohio, Cincinnati, 1863; aged 81; a veteran of the Civil War; a member of the Royal Society of Medicine, London, England, and Cincinnati Academy of Medicine; at one time health officer of Cincinnati; died at the home of his brother-in-law in that city, September 8.

Oliver Willard Sinclair, M.D. New York University, New York City, 1889; McGill University, Montreal, 1891; aged 46; a Fellow of the American Medical Association; one of the owners of the Sequoia Hospital, Eureka, Calif.; was killed in that city September 15, in a collision between his automobile and a railway train.

George Francis McCutcheon Lamont, M.D. Long Island College Hospital, 1896; aged 42; of Newark, N. J.; a Fellow of the American Medical Association and a well known specialist on diseases of the eye, ear, nose and throat; was drowned off Sandy Hook, N. J., September 19 by the capsizing of a motor boat.

Andrew Lawson Grieve, M.D. Bellevue Hospital Medical College, 1898; aged 38; formerly of New Bedford, Mass.; fell or jumped from a third-story window in Providence, R. I., September 11, was impaled on a picket fence and died a few hours later in St. Luke's Hospital, Providence, from his injuries.

Robert Scott Wiley, M.D. Medical College of Virginia, Richmond, 1872; University of Maryland, Baltimore, 1875; aged 69; a member of the Medical Society of Virginia; for thirty-five years a practitioner of Allegheny County, Va.; died at his home in Covington, Va., September 4.

Henry F. Kortebein, M.D. Northwestern University Medical School, Chicago, 1892; aged 46; formerly a member of the State Medical Society of Wisconsin and a well known practitioner of Milwaukee; died at the Oconomowoc Health Resort, near Nashotah, Wis., September 14.

David M. Smith (license, certificate, Missouri, 1884), aged 80; for forty-six years a practitioner of Wright County, Mo.; was thrown from his horse, September 10, the horse falling on him and crushing him; and died from his injuries at his home near Hartsville, Mo., a few hours later.

Frank Mason Putnam, M.D. Dartmouth Medical School, Hanover, N. H., 1878; aged 62; of Gardiner, Me.; director of the National Bank of Gardiner, and chairman of the board of selectmen of Farmingdale; died at his home in Gardiner, September 1.

Jeremiah Campbell Foster, M.D. Hahnemann Medical College, Philadelphia, 1892; aged 44; of Columbus, Ohio; adjuster for Ohio and West Virginia for the Order of Ben Hur; died in Grant Hospital, Columbus, September 14, from heart disease.

George Wall, M.D. Rush Medical College, 1889; aged 63; a Fellow of the American Medical Association and for more than twenty-five years a practitioner of Oregon; died at his home in Cottage Grove, Ore., September 10, from cerebral hemorrhage.

James Sullivan, M.D. College of Physicians and Surgeons, Chicago, 1891; for many years a practitioner of Tama, Ia., but for the last year a resident of Muscatine, Ia.; died at the home of his brother in Machias, Me., September 2, from pneumonia.

Frederick Darius Bickford, M.D. University of Michigan, Ann Arbor, 1882; aged 54; for many years a practitioner of Ogden and Salt Lake City, Utah, but for the last year a resident of Fillmore, Utah, died in that place, September 10.

Walker Schell, M.D. Miami Medical College, Cincinnati, 1878; aged 59; a Fellow of the American Medical Association and a prominent practitioner of southern Indiana; died at his home in Terre Haute, Ind., September 13, from ptomain poisoning.

John Lester Sivert, M.D. University of Nashville, Tenn., 1909; aged 33, of Georgetown, W. Va.; was found dead in his office in Georgetown, September 13, from the effects of poison believed to have been self-administered with suicidal intent.

James W. Wallace, M.D. St. Louis College of Physicians and Surgeons, 1893; aged 55; of Greenway, Ark.; died at the home of his father-in-law in Paducah, Ky., August 28, from uremia and cirrhosis of the liver, August 29.

John G. McGuire, M.D. Jefferson Medical College, 1861; aged 88; until 1895, a practitioner and druggist of Anamosa and Mechanicsville, Ia.; died at the home of his son in Chicago, September 5, from cerebral hemorrhage.

Ralph F. McHenry, M.D. University of Pittsburgh, Pa., 1895; aged 46; a Fellow of the American Medical Association; chief surgeon of the Windber, Pa., Hospital; died in Windber, September 14, from typhoid fever.

Samuel B. Limerick, M.D. Kansas City, Mo., Medical College, 1876; aged 61; a pioneer practitioner of Snohomish, Wash., but since 1898, a resident of Seattle; died in Providence Hospital, Seattle, September 11.

Philander F. Wellman (license, Kansas, 1901), aged 77; of Coffeyville, Kan.; a practitioner of southern Kansas for more than thirty years; died at the home of his son in Kansas City, Kan., September 16.

George T. Prince, M.D. University of Tennessee, Nashville, 1887; aged 50; a resident of Chattanooga, Tenn., for ten years; died at his home in St. Elmo, Chattanooga, September 16, from acute gastritis.

Elias S. Boyd (license, Texas, Fifth Judicial District Board, 1887); aged 66; a practitioner and Presbyterian clergyman of Texas since 1880; died at his home in Dallas, September 10.

Granville Prizer, M.D. University of Pennsylvania, Philadelphia, 1868; aged 70; at one time Register of Wills of Chester County, Pa.; died at his home in Lionville, Pa., September 7.

Carl N. McCaslin, M.D. Medical College of Indiana, Indianapolis, 1902; aged 39; of Earl Park, Ind.; died in the Washington Park Hospital, Chicago, September 17, from peritonitis.

Tyrer Harris Hassell, M.D. University of Louisville, Ky., 1885; aged 53; a member of the Tennessee State Medical Association; died at his home in Springfield, Tenn., September 11.

Joseph M. Wolf, M.D. University of Louisville, Ky., 1870; aged 74; for many years a practitioner of Arkansas, but since 1895, a resident of Texas; died at his home in Rockdale, Tex., August 30.

Henry Lehmann, M.D. New York University, New York City, 1881; aged 56; formerly a practitioner of New York City; died at his home in Brooklyn, September 13, from diabetes.

Philander Noffsinger Hardman (license, years of practice, Iowa, 1887), aged 74; a veteran of the Civil War; died at his home in Sigourney, Iowa, September 6, from valvular heart disease.

William Andrew Walker (license, Kansas, 1901), aged 82; an eclectic practitioner of Galena, Kan.; died at the home of his son in that city, September 15, from cerebral hemorrhage.

Andrew J. Stokes, M.D. Western Reserve University, Cleveland, 1882; aged 56; of Jersey Shore, Pa.; died at a cottage on Pine Creek, near Jersey Shore, September 7.

Newton Rodger McLean, M.D. Medico-Chirurgical College of Philadelphia, 1904; aged 38; died suddenly at his home in Bolivar, Pa., September 12, from heart disease.

Josiah Candor McLaughlin, M.D. College of Physicians and Surgeons, Kansas City, Kan., 1901; aged 50; died at his home in Kansas City, Mo., September 11, from nephritis.

Aquila A. Washburn, M.D. Jefferson Medical College, 1881; aged 56; a member of the Indiana State Medical Association; died at his home in Clinton, Ind., September 16.

William Hardin Boals, M.D. Rush Medical College, 1877; aged 65; of Minneapolis; died in the Eitel Hospital in that city, September 10, after a surgical operation.

William T. Boyd (license, Maryland), aged 55; of Upper Falls, Md.; died at the home of his father in Lebanon, Pa., from disease of the lungs, September 14.

Sidney W. Walters, M.D. Bennett Medical College, Chicago, 1898; aged 51; formerly of Goshen, Ind.; died at his home in Chicago, September 13.

Alvin Steel Davidson (license, Blount County, Ala., 1876), died at his home in Oneonta, Ala., September 2.

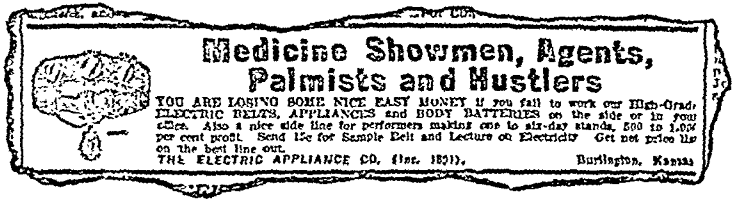
The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

ADDISON'S GALVANIC ELECTRIC BELT

While the electric-belt fake has lost the vogue it once had, that class of the community to which the late Mr. Barnum so feelingly referred is still in evidence. This, at least, is the impression one gets from an advertisement that appeared in a weekly publication devoted to the "show world"—the *Billboard*—and here reproduced:



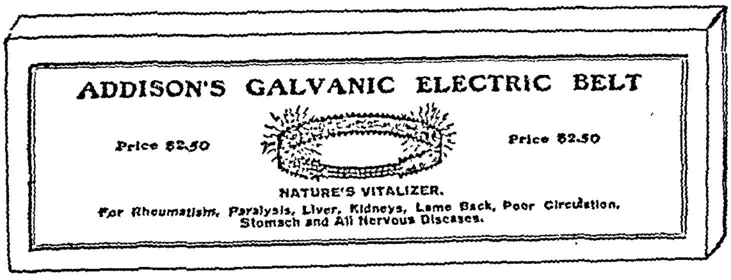
Medicine Showmen, Agents, Palmists and Hustlers

YOU ARE LOSING SOME NICE EASY MONEY if you fail to work our High-Grade ELECTRIC BELTS, APPLIANCES and BODY BATTERIES on the side or in your office. Also a nice side line for performers making one to six-day stands, 500 to 1,000 per cent profit. Send 15c for Sample Belt and Lecture on Electricity. Get net price list on the best line out.

THE ELECTRIC APPLIANCE CO. (Inc. 1891), Burlington, Kansas

This makes interesting reading, especially as the *Billboard* has editorially declared that its "advertising columns are as carefully edited and the offers that get into them are as closely scrutinized as jealous care, scrupulous honesty and constant vigilance can ensure." Further the *Billboard* has said: "We print no swindling patent medicine ads . . . in fact no catchpenny or petty larceny business whatever."

In view of this, it seemed worth while to send fifteen cents to the Electric Appliance Company for the "sample belt and lecture on electricity." The belt came, also the "lecture," to say nothing of a miscellaneous assortment of advertisements of medical or quasi-medical devices. Cheap and tawdry was the belt but a most gorgeous affair, withal. Strips of vivid red and yellow cotton crudely put together and enveloping small pieces of copper and zinc separated by blotting paper. This last, of course, to generate the electric current. The "lecture on electricity" was a gem: "Did not time prevent, we could talk for hours upon the many wonderful things that electricity has accomplished. . . . Electricity contains all the elementary principles and therefore all the healing properties of all things in being. All the balms, oils and minerals in existence are contained in electricity and in their most skillfully combined proportions. . . . If you are weak you need electricity. For lost womanhood or manhood there is nothing like electricity to restore your health. To the ladies we will say, if you have female pains there is nothing better than an electric belt. . . . Electricity is the greatest power on earth. It puts life and force into whatever it touches; gives relief to rheumatism, backache, kidney, liver and bladder troubles, early decay, night losses, lack of nerve and vigor, nervous debility, constipation, dyspepsia, undevelopment and lost vitality and all female complications."



ADDISON'S GALVANIC ELECTRIC BELT
Price $2.50
Price $2.50
NATURE'S VITALIZER.
For Rheumatism, Paralysis, Liver, Kidneys, Lame Back, Poor Circulation, Stomach and All Nervous Diseases.

Miniature reproduction of the package containing the ten-cent electric belt.

All this, of course, leading up to the sale of the Addison Galvanic Electric Belt, which comes in a neat little box, on which is plainly printed the price, $2.50. And this electrical marvel may be purchased from the manufacturers, the Electric Appliance Company, for the trivial sum of $1.10 *a dozen—less than ten cents each.* Question: How much "*nice easy money*" have the "*medicine show men*" taken in this season in selling for $2.50 an "Addison Galvanic Electric Belt" that costs less than ten cents and isn't worth anything?

ARTICLES REFUSED RECOGNITION

Reports of the Council on Pharmacy and Chemistry

Below appear abstracts of the Council's action on articles refused recognition which were not deemed of sufficient importance to require a lengthy report. A star opposite a title indicates that a more extensive report on the article in question will appear in the Reports of the Council on Pharmacy and Chemistry, 1915, and that a reprint of the report in question will be sent on receipt of a 2-cent stamp.

Iodum-Miller*

Iodum-Miller (Iodum-Miller Company, Kansas City, Mo.) is advertised to physicians under the implied claim that the preparation is new and original. It is said to be made from "Soot Iodin." What "Soot Iodin" is, the company does not explain beyond making the statement that it is made from "Resublime" iodin and is soluble in water. According to the label:

> ". . . 45 drops equals 1 dr. by weight. Each drop equals the per cent. of iodin in 1 gr. potas. iodid."

Iodum-Miller, when analyzed in the Chemical Laboratory of the American Medical Association, was found to be essentially a solution of iodin and potassium iodid in glycerin. This, of course, disposes of the implied claim that it should be regarded as something new and original. It was found to contain 1.68 per cent. of free iodin and 1.80 per cent. potassium iodid. If the company's statement that 45 drops of Iodum-Miller weigh 1 dr. is correct, then it is obvious that 1 drop of the product equals the percentage, not of 1 gr. potassium iodid, as claimed, but of only 1/20 gr. potassium iodid. This being the case the statement on the label is manifestly false and should constitute misbranding under the federal Food and Drugs Act.

Iodum-Miller is recommended for internal use in doses from ½ drop to 20 drops which, as the examination shows, is equivalent to from 1/40 grain to 1 grain potassium iodid. Yet, the use of this product is suggested in:

> "Pneumonia, Tuberculosis, Pleurisy, Typhoid Fever, Syphilis, Catarrh of Mucous Surface of Alimentary Canal, Autotoxemia, Vomiting of Pregnancy, Rheumatism, Chronic Glandular and Organic Affections."

Its external or germicidal efficacy may be measured by the free-iodin content. The laboratory's analysis showed that this is less than one third of that of tincture of iodin. Nevertheless, Iodum-Miller is recommended for external application in:

> "Pleurisy, Cough, Sore Throat, Pyorrhea . . . Blood Poison, Diseases of Uterus and appendages . . . Gonorrhea . . . Orchitis, Bubo, Prostatitis, Swellings, Enlarged Glands, Etc."

The therapeutic claims made for Iodum-Miller are so obviously extravagant that they need no discussion. The case against this product may be summed up thus: (1) Incorrect statements are made regarding its composition; (2) the therapeutic claims made for it are unwarranted, and (3) the application of a trade name to an established non-proprietary product (glycerin solution of iodin) is unjustifiable. In view of these facts the Council held Iodum-Miller ineligible for New and Nonofficial Remedies.

Iod-Izd-Oil (Miller's)*

Iod-Izd-Oil (Miller's) is said to be an "iodin combination" made "from the same Soluble Soot Iodin as in Iodum Miller." It is said to "liberate Free Soluble Iodin" when applied to the skin, mucous surfaces, etc. It is further defined as "Soluble Iodin combined with water-white Hydrocarbon Oil" and is said to liberate "Soluble Iodin 2 per cent." While these statements suggest that Iod-Izd-Oil (Miller's) contains the iodin-potassium-iodid combination contained in Iodum-Miller, analysis indicated the oil to be a simple solution of iodin in liquid petrolatum. Quantitative determinations indicated, not 2 per cent. of iodin, as claimed, but only 0.42 per cent. and all of this was present as free iodin.

Iod-Izd-Oil (Miller's) is refused recognition because the composition is not correctly stated and because the application of a trade name to an established non-proprietary product tends to confusion.

Hexa-Co-Sal-In

Hexa-co-sal-in (Hexa-Co-Sal-In Company, Red Bank, N. J.) is advertised as "a condensation product of familiar composition." The further explanation that it is "colchi-magnesium salicylate with anhydrous hexamethylenamin" does not make this statement much clearer. "Colchi-magnesium salicylate"—not to speak of its condensation product with hexamethylenamin—is unknown in chemical literature. As a matter of fact, an examination made by the Chemical Laboratory of the American Medical Association shows that Hexa-co-sal-in is a simple mechanical mixture of hexamethylenamin, magnesium salicylate and some colchicum preparation. The composition is therefore falsely stated.

The preparation is advertised as:

"Antirheumatic, Antineuritic, Urinary Antiseptic."
"Uric Acid Mobolizer" (sic).
"Intestinal Antiseptic, Mildly Laxative."
"Whenever a salicylate is indicated use Hexa-co-sal-in."

The combination of salicylates, hexamethylenamin and colchicum in a routine formula is certainly inadvisable: where one of the ingredients is needed, the others may be useless or even harmful. The unqualified advice to use hexamethylenamin and colchicum "whenever a salicylate is indicated" is likely to do harm.

The statement of the composition of this preparation is false; unwarranted therapeutic claims are made for it, and the mixture is unscientific. The Council held Hexa-co-sal-in ineligible for New and Nonofficial Remedies because of conflict with Rules 1, 6 and 10.

Correspondence

Eye Headaches

To the Editor:—Dr. W. F. Cheney has recently written an article entitled "Gastric Headaches" (*Am. Jour. Med. Sc.*, May, 1915, p. 656) which should not go unchallenged on account of an apparent backward step in teaching that recurrent headaches, serious causes being excluded, are due to the stomach and not to the eyes. The poor stomach of civilized humanity has been long maltreated for headaches, and it is a pity to revive such treatment.

That a bad stomach can cause a headache is true, but never a headache that puts a patient to bed and out of business. A headache due to an overdose of alcohol is not due to the upsetting of the stomach, but to the action of alcohol on the brain. That going without food and purging will cure an eye headache is true; so will time. There is no anatomic reason for a stomach to cause a one-sided headache (instanced by Cheney), and there is good reflex reason why any headache may cause retarded digestion, nausea and vomiting. Recurrent eye pains can cause all kinds of gastric disturbances, hyperchlorhydria, etc.

In Cheney's Case 1 he took a hardworking office man and made him take more exercise out of doors, i. e., reduced his hours of eye work. The patient improved as to his headaches.

In Case 2 Cheney stopped the man's alcohol and reduced his tobacco, both of which cause a weakening of the eye muscles; the patient got better of his headaches.

In Case 3, the glasses did the girl no good, and there was "a chronic gastritis of the subacidity type." Cheney does not say for what defect glasses were prescribed, whether or not the eyes were reexamined and the glasses found correct, or whether the patient still wore glasses after the stomach treatment began or whether she discarded them. He corrected a diet "which had been in every way improper both in quality and quantity." This regulation of the diet, with the tincture of nux vomica before meals and cascara at bedtime, stopped the headaches. There is no doubt that a patient subject to eyestrain headaches cannot abuse his stomach with impunity. This simply means that any toxin absorbed from the stomach or intestines may add the last straw to the resisting power of the eye-muscle balance, and a headache is the result.

I contend that if the eye defect is corrected the stomach, if not deliberately abused, will correct itself. On the other hand, no amount of treatment of the stomach, without correcting the eye defects or reducing the number of hours the eyes are used, or correcting a mal-use of the eyes, thus preventing eye tire, will stop migraine headaches.

A headache that is "periodical" "throughout months and years," "rarely lasting over twenty-four hours," in which "the patient awakens with pain in the morning," "growing more intense as the day goes on," or "it may come on in the evening," "may be so severe and prostrating as to incapacitate for any kind of work while they last," "sometimes nausea and vomiting," or "there may be no disturbance whatever of the stomach," is almost always an eyestrain headache and is probably very rarely a "gastric" headache.

OLIVER T. OSBORNE, M.D., New Haven, Conn.

To Aid the Expression of Dosage by the Metric System

To the Editor:—To facilitate the expression of dosage and solutions in the metric system, I desire to recommend a resort to two expedients with which we are all familiar.

First, as the cubic centimeter is a measure of capacity it should have a name. I propose the word "Ceci" (c.c.).

Second, let us disregard all such intermediate expressions as decigrams, centigrams, hundredths of a cubic centimeter, etc., and read all metric expressions in prescriptions in milles in precisely the same manner as we read our monetary expressions in cents. No one reads $1.50 as one and fifty-hundredths of a dollar, but as one dollar and fifty cents. Then 1.500 c.c. would be read one ceci, five hundred milles; millececi being understood. And 5.080 grams would be read five grams and eighty milles; milligram being understood.

Also as we never write one dollar ten cents thus, $1.1, but always thus, $1.10, so we should always have the three places in our metric prescriptions thus, 1.700 gm. and never 1.7 gram. This for clarity and uniformity.

FRANK THOMAS WOODBURY, M.D., Camp Gaillard, C. Z.

The Sweet Potato as an Aphrodisiac

To the Editor:—In a recent editorial [THE JOURNAL, Sept. 11, 1915, p. 957] on the "Sugars of the Sweet-Potato" you cite a quotation from the "Merry Wives of Windsor" as evidence that Shakespeare classed the sweet potato with sweetmeats. Let me suggest another interpretation.

The full quotation reads: "Let the sky rain potatoes; let it thunder to the tune of 'Green Sleeves'; hail kissing-comfits and snow eringoes; let there come a tempest of provocation, I shelter me here (embracing Mrs. Ford)." All three edibles above mentioned were, during Shakespeare's time, considered aphrodisiac, as truffles are today by the laity. The whole situation of the scene together with the allusion to the tune of "Green Sleeves" (a lascivious song) proves the correctness of my contention.

GEORGE MINGES, M.D., Dubuque, Iowa.

Transverse Incision in Operation for Appendicitis

To the Editor:—In reading Dr. A. E. Rockey's paper (THE JOURNAL, Sept. 11, 1915, p. 939), I was struck by the fact that no mention was made by the author, or any of those who discussed the paper, of an important point brought out first, I think, by Professor Kocher of Berne, Switzerland: so far as possible to make the incision follow the line of skin cleavage. This line is transverse or nearly so in the lower abdomen, and when followed, the wound heals better, with a much narrower scar, and far less danger of postoperative hernia. This method has been followed by Babcock of Philadelphia for several years, with excellent results.

R. PENN SMITH, M.D., Pittsburgh.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. *Every letter must contain* the writer's name and address, but these will be omitted, on request.

JUDGMENT FOR DAMAGES—HERNIA—UNDER WORKMEN'S COMPENSATION LAW

To the Editor:—A man was injured in the mines and among his injuries a hernia developed. The employers refused to compensate this man any more than to the amount of $2.75, the price of a truss. He has brought suit. In a journal which I am unable to locate I find that a man got judgment in another state against the industrial commission of that state. Can you give me any reference to this case, or to any similar cases?

John Caldwell, M.D., Rayland, Ohio.

Answer.—The questioner has failed to state whether or not the person injured was working under the workmen's compensation law. If he was working under the compensation law, that law determines the amount of compensation to which he is entitled, and that amount can be recovered without necessity of entering suit. If he was not under the compensation law, he would have to sue under the common law.

Industrial commissions are administrative (and in some states quasi judicial) bodies appointed to administer the workmen's compensation law, and could not be sued by an injured person for compensation. The questioner, therefore, must be in error about judgment having been obtained against an industrial commission of some state for compensation due an injured workman.

In the case mentioned it is quite likely that the employers refuse to pay compensation for the reason that they believe the hernia was not the result of an accident. It is very common for workmen who receive an injury to claim that as a result of the injury a hernia developed, when as a matter of fact the hernia was present before the injury was received. Many cases of this kind have been tried under the common law as well as under workmen's compensation acts, with decisions varying, naturally, according to the facts in each particular case.

HERPES ZOSTER ON MUCOUS MEMBRANES

To the Editor:—Does herpes zoster occur in the buccal mucous membrane? A case was shown recently in the New York Post-Graduate School in which there had been vesicles on the inner surface of the mouth. These had been diagnosed as herpes zoster, but when the patient was shown to the class the vesicles had disappeared, leaving deep depressions on the inner surface of the cheek.

Julian L. Kendall, M.D., New York City.

Answer.—When there is involvement of the second branch of the fifth nerve, the eruption of herpes may occur on the cheek, side of the nose, and one-half of the upper lip. In exceptional cases, it may occur also on the mucous membranes of the cheek and pharynx. Loss of the teeth and necrosis of the jaw have been noted as rare complications.

LACTATION DURING PREGNANCY

To the Editor:—Pardon my suggesting that in your reply to the query of Dr. Norman (The Journal, August 21), you pass too lightly over the possible bad effects to the infant of nursing during pregnancy.

While so far as I know, none of the standard authorities consider that deleterious substances are present in the milk as a result of pregnancy, there is practical unanimity among them in ascribing frequent bad results to infants nursing from the breasts of pregnant mothers. That this is not always due to nervous impressions is attested by the fact that there is not infrequently a deterioration in the mother's milk, even when she is ignorant of her pregnancy. That the decreased value of the milk of a pregnant woman may be due to a diminished supply or to an abnormal quantitative variation in normal constituents does not alter the fact of its undesirability as an infant's diet. Nor does it follow, because pregnancy does not always cause a deterioration of the milk, that it never does, any more than we can assume, because the laity are usually wrong on medical matters, that they are always wrong.

In lieu of further discussion of this question, I beg to refer you to the texts of Pfaundler and Schlossman, Rotch, Holt and others, who are not without reputation in the field of pediatrics. If, in the light of present-day knowledge, it is a matter of little or no consequence to the welfare of the nursling as to whether or not the mother *is pregnant,* it is the duty of pediatricians to lose no time in instructing, not the laity, but a large body of earnest and able general practitioners.

Benjamin H. Brown, M.D., *Muskogee,* Okla.

Answer.—There is no scientific proof of the theories advanced by our correspondent. While it is possible that in certain instances on the incidence of pregnancy the milk does deteriorate, that is not proof that the deterioration is due to the presence of the pregnancy. It would be a matter of clinical importance to determine whether pregnancy in itself without any attendant nervous phenomena produces the deterioration of milk which our correspondent suggests as a possibility. It is an unquestionable fact that a fair proportion of mothers nurse their babies until they learn of the presence of the pregnancy. It has never been possible by chemical analysis to determine any deleterious substances in the milk of pregnant women. Such substances, of course, may not be subject to discovery in this matter, but it would seem to be far wiser to assume that the pregnancy is not to blame for the disturbance in the infant or decrease in the flow of milk, and to seek in all instances to attribute this to some other cause. Certainly more harm can be done by assuming that pregnancy is deleterious to nursing than by assuming the opposite, and the question of the middle ground is at least debatable.

THE CLINICAL USE OF RADIUM

To the Editor:—Please inform me where I can secure literature on the clinical use of radium.

A. A. Ashby, M.D., Red Oak, Iowa.

Answer.—A list of references on this subject was published in The Journal for Oct. 18, 1913, *p. 1475.* The following articles have appeared subsequently to that date:

TREATMENT OF BEE STINGS

To the Editor:—Referring to query of Dr. Kettelkamp, under this heading (The Journal, Sept. 11, 1915, p. 972), I had a similar case and recognizing the evidences of anaphylaxis I gave 10 minims of epinephrin hypodermically with almost immediate relief. This may not be invariably successful, but I believe it is worth trying in such cases.

Frank L. Wood, M.D., Lynden, Wash.

Compensations in Medicine.—For scientific interest the field in medicine is large, and the reward comes in achievement, but the compensation otherwise is negligible. Problems of all sorts develop for the laboratory man as well as for the clinician in medicine and their solution is worth while, but not profitable.—Isadore Dyer, M.D., *New Orleans Medical and Surgical Journal.*

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Arizona: Phoenix, October 5-6. Sec., Dr. John Wix Thomas, 200 National Bank of Arizona Bldg., Phoenix.

Arkansas: Regular, Little Rock, November 9-10. Sec., Dr. T. J. Stout, Brinkley. Homeopathic, Little Rock, November 11. Sec., Dr. Scott C. Runnels, 900 Scott St., Little Rock.

Colorado: Denver, October 5. Sec., Dr. David A. Strickler, 612 Empire Bldg., Denver.

Connecticut: Regular, New Haven, November 9-10. Sec., Dr. Charles A. Tuttle, 196 York St., New Haven. Homeopathic, New Haven, November 9. Sec., Dr. Edwin C. M. Hall, 82 Grand Ave., New Haven. Eclectic, November 9. Sec., Dr. T. S. Hodge, 19 Main St., Torrington.

District of Columbia: Washington, October 12. Sec., Dr. Edgar P. Copeland, The Rockingham, Washington.

Georgia: Atlanta, October 12. Sec., Dr. C. T. Nolan, Marietta.

Idaho: Wallace, October 5. Sec., Dr. C. A. Dettmen, Burke.

Illinois: Chicago, October 13-15. Sec., Dr. C. St. Clair Drake, Springfield.

Iowa: Des Moines, October 19-21. Sec., Dr. Guilford H. Sumner, State House, Des Moines.

Kansas: Topeka, October 12-14. Sec., Dr. H. A. Dykes, Lebanon.

Maine: Portland, November 9-10. Sec., Dr. Frank W. Searle, 776 Congress St., Portland.

Michigan: Lansing, October 12-14. Sec., Dr. B. D. Harison, 504 Washington Arcade, Detroit.

Minnesota: Minneapolis, October 5-8. Sec., Dr. Thomas S. McDavitt, 814 Lowry Bldg., St. Paul.

Mississippi: Jackson, October 26-27. Sec., Dr. E. H. Galloway, Jackson.

Montana: Helena, October 5. Sec., Dr. William C. Riddell, Helena.

Nebraska: Lincoln, November 10-11. Sec., Dr. H. B. Cummins, Seward.

Nevada: Carson City, November 1. Sec., Dr. Simeon L. Lee, Carson City.

New Jersey: Trenton, October 19-20. Sec., Dr. G. H. Norton, 429 E. State St., Trenton.

New York: Albany, Buffalo, New York, Syracuse, October 5-8. Mr. Harlan H. Horner, Chief, Examination Division, State Education Bldg., Albany.

Oklahoma: Oklahoma City, October 12. Sec., Dr. Ralph V. Smith, 502 Daniel Bldg., Tulsa.

Porto Rico: San Juan, October 4. Sec., Dr. Quevedo Baez, Allen St., San Juan.

Rhode Island: Providence, October 7-8. Sec., Dr. Gardner T. Swarts, State House, Providence.

South Carolina: Columbia, November 9. Sec., Dr. A. Earle Boozer, 1806 Hampton St., Columbia.

Texas: Dallas, November 9-11. Sec., Dr. M. P. McElhannon, Belton.

Utah: Salt Lake City, October 4-5. Sec., Dr. G. F. Harding, 407 Templeton Bldg., Salt Lake City.

West Virginia: Elkins, November 9. Sec., Dr. S. L. Jepson, Charleston.

Wyoming: Laramie, October 13-15. Sec., Dr. H. E. McCollum, Laramie.

Montana April Report

Dr. William C. Riddell, secretary of the Montana Board of Medical Examiners, reports the written examination held at Helena, April 6-8, 1915. The total number of subjects examined in was 10; total number of questions asked, 50; percentage required to pass, 75. The total number of candidates examined was 34, of whom 23 passed and 11 failed. The following colleges were represented:

PASSED

College	Year Grad.	Per Cent.
Bennett Medical College	(1913)	77.8
Hering Medical College	(1910)	77.6
Northwestern University	(1912)	76.5
Rush Medical College	(1905) 85.2; (1908) 80.7; (1913) 84; (1914)	84.4
Medical College of Indiana	(1904)	76.2
Keokuk Medical College, Coll. of Phys. and Surgs.	(1903)	80.4
State University of Iowa, College of Medicine	(1897)	76.4
Tulane University of Louisiana	(1914)	81.8
College of Phys. and Surgs., Baltimore	(1913) 80.2; (1914)	79.9
Kansas City Hahnemann Medical College	(1909)	76.1
Washington University, St. Louis	(1914)	85.3
John A. Creighton Med. Coll.	(1905) 79.7; (1913) 77.6; (1914)	83.2
Jefferson Medical College	(1914)	78.1
University of Tennessee	(1907)	75.1

Minnesota June Report

Dr. Thomas S. McDavitt, secretary of the Minnesota State Board of Medical Examiners, reports the oral, practical and written examination held at Minneapolis, June 1-4, 1915. The total number of subjects examined in was 18; total number of questions asked, 80; percentage required to pass, 75. The total number of candidates examined was 44, of whom 42 passed and 2 failed. Six candidates were licensed through reciprocity. The following colleges were represented:

PASSED

College	Year Grad.	Per Cent.
Rush Medical College	(1914) 86; (1915) 82,	87
Johns Hopkins University	(1913)	84
Harvard University	(1915)	87
Hamline University	(1904)	75
University of Minnesota	(1914) 84, 85, 87; (1915) 81, 82, 84, 85, 85, 86, 86, 86, 86, 87, 88, 88, 88, 88, 88, 89, 89, 90, (1916)* 83, 84, 84, 85, 85, 86, 86, 86, 86, 86, 87 87, 87, 88,	90.

FAILED

College	Year Grad.	Per Cent.
University of Louisville	(1909)	74
Hamline University	(1904)	71

LICENSED THROUGH RECIPROCITY

College	Year Grad.	Reciprocity with
Northwestern University	(1910)	Illinois
Rush Medical College	(1903)	Illinois
Sioux City College of Medicine	(1905)	Iowa
University of Minnesota	(1910)	S. Dakota
Medical College of Virginia	(1914)	Virginia
Marquette University	(1913)	Wisconsin

* These candidates have completed a four year college term, but their diplomas are withheld pending the serving of a year's internship in an approved hospital.

South Dakota July Report

Dr. Park B. Jenkins, secretary of the South Dakota State Board of Health and Medical Examiners, reports the practical and written examination held at Pierre, July 13-14, 1915. The total number of subjects examined in was 15; total number of questions asked, 95; percentage required to pass, 75. The total number of candidates examined was 11, all of whom passed. Four candidates were licensed through reciprocity. The following colleges were represented:

PASSED

College	Year Grad.	Per Cent.
George Washington University	(1909)	82.3
College of Physicians and Surgeons, Chicago	(1907)	84
Northwestern University	(1914)	93.3
Rush Medical College	(1911) 88.7; (1914) 85.2, 88; (1915)	90.7
Detroit College of Medicine	(1895)	81.4
University of Minnesota	(1915)	83.4
University of Nebraska	(1912)	85.7
University of Vienna	(1912)	84.5

LICENSED THROUGH RECIPROCITY

College	Year Grad.	Reciprocity with
University of Minnesota	(1913, 2) (1914)	Minnesota
Woman's Medical College of Pennsylvania	(1912)	Colorado

The following questions were asked:

OBSTETRICS

1. Describe the female pelvis and name the bones composing the same. 2. Give cause, symptoms and treatment for puerperal eclampsia. 3. (a) What is menstruation? (b) What is vicarious menstruation? 4. How does the embryo receive nourishment? 5. Does the maternal blood enter the circulation of the child; if so, how? 6. How would you proceed when the placenta cannot be removed? 7. (a) What is abortion? (b) Miscarriage? (c) Premature labor? (d) Give treatment of threatened abortion. 8. What are the causes of albuminuria and edema during pregnancy? How would you treat the former? 9. What are the duties of a physician in a case of labor? 10. Give treatment of placenta prævia when occurring before full term.

EMBRYOLOGY, HISTOLOGY AND ANATOMY

1. From what embryonic layer is the skin developed? Name all other structures developed from the same layer. 2. Describe a fetus at third month. 3. Detail histology of the skin. Make a drawing showing a hair-follicle. 4. Detail histology of adrenal gland. Where are they located? 5. Locate the thyroid gland. Give its function, blood and nerve supply. 6. Describe and locate the ethmoid bone. 7. Name the bones of the tarsus. 8. Describe the ankle-joint. 9. Describe the axilla and name its contents. 10. Give origin, course and distribution of the seventh and eighth dorsal nerves.

PATHOLOGY

1. Describe the gross appearance of the kidney in chronic interstitial nephritis. 2. How does calcareous degeneration of the arteries influence the circulation? 3. (a) What is understood by the phrase "new formation"? (b) Define the term malignant as applied to new formations. 4. What are the pathologic appearances of anemia of the brain? 5. Is cerebrospinal fever more generally sporadic or endemic? 6. What is cretinism, and with what is it associated? 7. What pathologic conditions increase the elimination of urea? 8. Describe how mitral stenosis and aortic regurgitation respectively affect the cavities and musculature of the heart. 9. Describe the formation of an acute abscess. 10. (a) On what principals are tumors classified? (b) Mention the important classes of tumors, giving an example under each class.

REGULAR THERAPEUTICS AND PRACTICE

1. What are the symptoms and signs present in acute articular rheumatism with endocarditis? 2. Give in detail, the dietetic and hygienic rules and regulations you would prescribe in a case of diabetes mellitus. 3. Explain the difference between the principals underlying vaccine therapy and serum therapy. State the character of danger in their application to the human body. 4. Give the temperature chart in each of the following diseases: (a) Typhoid fever, terminating in recovery; (b) croupous pneumonia, terminating in recovery; (c) intermittent fever (quotidian); (d) variola, terminating in death on the twelfth day. 5. Give the incubation periods of measles, scarlet fever, smallpox and chicken-pox. 6. On what theories or principles are cold baths and cold sponging resorted to? State the indications calling for such measures. 7. How would you diagnose a case of diphtheria? Describe the treatment in detail and tell when it would cease to be infectious. 8. (a) Give the therapeutic application of drugs in the different stages of pneumonia. (b) Give the comparative value of chloroform and ether as an anesthetic. 9. In the treatment of chronic interstitial nephritis, what dietetic and hygienic suggestions would you make? Name three drugs that might be employed in the treatment of this condition, with the precise reason for the employment of each. 10. In what pathologic conditions is digitalis indicated and contraindicated? Describe its action.

SURGERY

1. Differentiate between congestion and inflammation. 2. What do you understand by a dissecting aneurysm? 3. What agents are employed for the production of local anesthesia? 4. Describe the operation of exposing the brachial artery for ligation at any selected point. 5. Describe a method of reducing a backward dislocation of the forearm. 6. What would be your treatment of a fracture at the base of the skull? By what symptoms would you base your diagnosis? 7. Describe the operation for the correction of a cleft palate. 8. What site should be selected in performing a paracentesis? 9. Give symptoms and treatment of hammer-toe. 10. Differentiate between appendicitis and renal colic from the standpoint of pain, tenderness, vomiting, urine and Roentgen-ray examination.

PHYSIOLOGY

1. (a) Give functions of gallbladder. (b) When is the bile thrown into the stomach and how? 2. Give the principal characteristics of the digestive juices. 3. (a) What is the difference between the sebaceous and sudorific glands? (b) Where found and their functions? 4. (a) What is the object of respiration? (b) What changes, if any, take place in the blood during respiration? (c) What muscles enter into the mechanism of respiration? 5. (a) Describe fetal circulation. (b) How many circulations during fetal and adult life? 6. What are the various functions of the liver? 7. Name the chief ductless glands and give functions of the same. 8. (a) What is meant by secretion? (b) What is meant by excretion? Give examples. 9. (a) How do the veins differ from the arteries? (b) How is the onward flow of blood maintained in the veins? 10. Give the varieties of connective tissue and where found and their functions.

CHEMISTRY

1. What is the average composition of air? Give chemical name, formula or symbol, valence and atomic weight of each constituent. 2. Give chemical name, symbol and physical properties of each of four gases, which would produce death if inhaled. 3. Give chemical names, symbols and physical properties of three gases having no bad effects if inhaled. 4. Complete the equations and give chemical names and physical properties of all new compounds formed. $Ba O_2$ plus $H_2 SO_4$ equals ? $Fe S$ plus $H_2 SO_4$ equals ? 5. Give chemical name, formula and physical properties of each: aqua fortis; aqua regia; aqua destillata; oil of vitriol; blue vitriol. 6. How much mercury is contained in ten grains of mercurous chlorid? The atomic weight of Hg being 200, and Cl 35. 7. What is formaldehyd chemically? Physical properties? How is it made? 8. Detail a test for strychnin. 9. Detail approximate estimation of urea. What reagent is used? What is the chemical reaction?

10. ℞ Hydrargyri chloridi mitis.................... gr. xv
Potassii iodidi .... dr. i
Aquae.............................q. s. ad oz. ii
Misce.

What change takes place? Describe the appearance of the mixture.

GYNECOLOGY

1. Give a probable cause and treatment of dysmenorrhea in a virgin, aged 16. 2. Detail how you would treat half a dozen interstitial fibroids of uterus, not hemorrhagic, age 30. Why? 3. Give symptoms and treatment of hyperthyroidism, without exophthalmos. 4. Give symptoms and treatment of extra-uterine pregnancy. 5. Give indication for curetment of endometrium.

HYGIENE AND SANITARY SCIENCE

1. What do you understand by malignant pustule and how would you handle the same? 2. Describe a method of aerated disinfection. 3. Describe the method of antityphoid vaccination. 4. Why is pure air more beneficial than polluted air? 5. Describe how infectious and contagious diseases are most commonly spread.

BACTERIOLOGY

1. By what laboratory methods may rabies be diagnosed? 2. Describe the *Bacillus tuberculosis*, its habitat, mode of growth and method of detection. 3. Give the function and products of bacteria. 4. (a) Give a general description of the action of agglutinins. (b) In what disease, other than typhoid, do agglutination reactions occur? 5. (a) Define ptomains. (b) Define leukomains.

SKIN AND GENITO-URINARY

1. Briefly describe eczema and give treatment. 2. Give cause, symptoms and treatment of carbuncle, intertrigo, hives. 3. Describe condylomata; give their cause and treatment. 4. Give causes, symptoms and treatment of enlarged prostate gland. 5. Describe the course of an attack of gonorrhea in the female and give treatment; mention complications which are probable.

EYE, EAR, NOSE AND THROAT

1. What is the Argyll-Robertson pupil and what does it indicate? 2. Give etiology, symptoms and treatment of trachoma. 3. Mention a half dozen common affections of the eyelids and give the treatment for them. 4. How would you treat gonorrheal conjunctivitis? 5. Give cause and treatment of chronic suppuration of the middle ear. 6. Give prophylactic treatment when mastoid disease is threatened. 7. Name at least four general diseases that affect the ear. 8. Diagnose retropharyngeal abscess and give the treatment for it. 9. Give indications for doing tracheotomy. Describe the operation. 10. How would you diagnose nasal polypi? Give treatment.

MEDICAL JURISPRUDENCE

1. How would you determine the distance from which a bullet wound from a revolver had been inflicted? 2. What stains would you look for in suspected poisoning by (a) an acid, (b) an alkali? Give the character of the stains. 3. What would be your duty, as a physician, when called to a case of suspected poison, either by accident, suicide or homicide? 4. How would you distinguish between a case of death by suicide resulting from ingestion of (a) carbolic acid, (b) hydrocyanic acid? 5. How would you determine whether an infant found dead in water had been immersed before death or after?

Book Notices

Alveolodental Pyorrhea. By Charles C. Bass, M.D., Professor of Experimental Medicine at the Tulane Medical College, and Foster M. Johns, M.D., Instructor in the Laboratories of Clinical Medicine at the Tulane Medical College. Cloth. Price, $2.50 net. Pp. 167, with 42 illustrations. Philadelphia: W. B. Saunders Company, 1915.

The authors start out with essentially the following premise. The *Endameba buccalis* is found in pus from pyorrhea pockets. Emetin hydrochlorid injected into a patient having "alveolodental pyorrhea" causes the protozoa to disappear; in addition, the clinical appearance of the tissues involved in the disease is much improved after its use; therefore *Endameba buccalis* is the cause of pyorrhea, and emetin hydrochlorid is specific for the disease. The statement is so positively made that one at first is lead to accept it. But Koch's laws have not been satisfied; there is room for doubt as to the accuracy of the premise. Many other organisms are present in pyorrhea pockets which may be the cause of the disease. These too may be influenced by emetin, either directly or by causing changes in the tissues, rendering them unsuitable for bacterial action; therefore, one cannot unqualifiedly accept without further proof the statement that the *Endameba buccalis* is the cause of pyorrhea alveolaris. Those who have followed the writings of Barret and Smith and Bass and Johns, and attempted to verify their findings, have found amebas very constantly present in pus from pyorrhea pockets; but they have also found them present in practically all unclean mouths in which pyorrhea does not exist. Motile amebas taken from pus pockets about the roots of teeth, and observed in salt solution on a warm stage, do not differ materially from those taken from unclean mouths which are free from pyorrhea.

The statement that pyorrhea alveolaris is cured by emetin also needs further evidence. That some patients are temporarily helped there is little doubt; but that the disease is cured permanently by this drug does not coincide with general experience, and this is admitted in the book, since relapse is indicated; besides, it is acknowledged that surgical means are demanded in some cases. If the peridental membrane be so far destroyed that local trea ment will not effect a cure, then no remedy which cann restore the investing membrane will be effective. The pe dental membrane being an organ, when once destroyed, ca not be restored, as is stated by the authors. This membra when once gone leaves no means of vital attachment of t gums or other approximating tissues to the tooth's roo therefore the pockets caused as a result of destruction of t peridental membrane must remain, unless surgically obl erated. Otherwise the pockets are a constant source of rei fection.

The book contains well-stated truths and not a few fallacies. That traumatism is a fruitful source of pyorrhea as stated there is no doubt, but Talbot and others believe that there are other causes. The authors have not observed the beneficial effects of good brushing of the teeth and gums with the tooth-brush, else they would not have dwelt on the bad results of the use of the tooth-brush, and recommended gauze for cleaning the teeth. Hyperemic gums are often cured by intelligent or rather vigorous use of a stiff tooth-brush. Gauze may merely transfer the débris about the teeth to the interproximal spaces, rendering a bad condition worse. Gingivitis may lead to pyorrhea alveolaris; but not all gingival irritations are pyorrhea alveolaris, as the authors seem to believe; still, amebas may be found in almost every instance in which the gums are irritated at their margins by unwholesome surroundings, such as salivary or serumal deposits, food débris, etc., although the peridental membrane may not be in the least involved. Such a gingivitis, unless dependent on systemic disease or metallic poisons, is readily cured by thorough cleansing and friction. Pyorrhea alveolaris is difficult to cure by any known means except in its early stages. The gums in health are a dense tissue capable of standing much rough usage; indeed, if the gums and teeth do not have plenty of exercise either by the use of coarse food or by brushing, then both gums and peridental membrane become hyperemic.

The authors say (page 45), "We think that almost all are infected before they are 20 years old." If it is meant that amebas may be found in most mouths, one can easily concur in this statement; but if it is meant that all adults have pyorrhea alveolaris, experience in treating diseases of the teeth and mouth does not agree with this conclusion. Differentiation between simple gingivitis and the disease of the peridental membrane, commonly known as pyorrhea alveolaris, should be sharply drawn, as there is a vast difference between the two. The authors do not appear to recognize this distinction.

The authors doubt whether salivary calculi cause inflammation of the gums, or whether the gum inflammation causes the formation of salivary calculi (page 155). Had there been some reading of Black, Talbot, Kirk and others on such subjects, there would have been fewer errors of this kind. A reading of these authors would have given information which would have demonstrated that salivary deposits may be found on parts of artificial plates and teeth which do not come in contact with gums diseased or otherwise, and also that deposits on the roots of teeth, rootwise from the free margins of the gums, are not of salivary origin, but are probably due to inflammation. The positive statement that pyorrhea alveolaris is caused by the endameba and that emetin hydrochlorid is specific for this disease is unfortunate. It has permitted enterprising drug manufacturers to flood physicians and dentists with literature copied from those who have made these positive statements and, as a result, the drug is being used indiscriminately without sufficient knowledge to justify it.

Human Herbivore and Carnivore.—Given the presence of the two human types in one locality, what may be expected of them? History provides abundant answer. Thus in England the square-jawed Roundheads under Cromwell stirred up the country for a few years and disappeared. The hatchet-faced Puritans found England too crowded and settled a new world. Today hawk-nosed bird men rule the upper air. The carnivore is the restless pioneer, inductive, dying ever on the outskirts in search of something new. The herbivore is the sedentary stabilizer, deductive, ever at his appointed task. Both are necessary to the progress of the world, and neither can do the work of the other. It seems unlikely that the human species will ever be reduced to one type, but should this come to pass one might hazard a surmise that the surviving type would be a mixed one, perhaps three parts carnivore and one part herbivore.—John Bryant, M.D., *Boston Med. and Surg. Jour.*, Sept. 9, 1915.

Miscellany

Causes of Death in Eminent Physicians

Hermann Vierordt, son of the founder of clinical sphygmography, has recently published a study of the causes of death of various medical celebrities (*Med. Klin.*, 1915, xi, 499, 525, 549) similar in character to his book (1893) on the abnormities and diseases of famous historical and literary characters (Medizinisches aus der Geschichte, Ed. 3, Tübingen, 1910). In 1907, the late Dr. William Pepper published a study of "Diseases of Great Physicians of the Past" (*Med. Lib. and Hist. Jour.*, 1907, v, 273) to which Vierordt's list, mainly German, may be regarded as supplementary, as most of his items are modern. Pepper gives us many quaint and curious details, such as the fact that Dr. Guillotin did not die of the guillotin, as is claimed; Dupuytren's statement that "he would rather end his life through God's hand than that of a surgeon"; Sir Theodore Mayerne's prediction of the time of his own death, and the fatal duel between Drs. Williams and Bennet of Jamaica (1750), which originated in a controversy about their views on the nature of bilious "fever."

Combining the data of Pepper and Vierordt, we find that the most common cause of death in these brain-workers is apoplexy, of which there are no less than thirty-six cases, including Scultetus (1645), Harvey (1657), Malpighi (1694), Ramazzini (1714), Linnaeus (1778), Stoll (1788), Monro 2d (1817), Jenner (1823), Pinel (1826), Young (1829), Sprengel (1833), Neissner (1860), Baudelocque (1864), Malgaigne (1865), Pfeuffer (1869), Carl Livi (1876), Stokes (1878), Buchheim (1879), Schwann (1882), Bevill Peacock (1882), Ritter von Rittershain (1883), Fechner (1889), Helmholtz (1894), Henke (1896), Fick (1901), Max Nitze (1906), Ponfick (1913) and Julius Pagel (1912). Physicians, no doubt from the drive and worry of their active lives, seem particularly liable to disorders of the circulation. Thus Lancisi (1820), Boerhaave (1738), Morgagni (1771), Currie (1805), Corvisart (1821), John Bell (1838), Richard Bright (1858), Bezold (1868), Ritter von Hoffmann (1897), Sir W. T. Gairdner (1907), Koch (1910) and Angelo Celli (1914) died of heart disease; John Hunter (1793), Sir Charles Bell (1842), Sir James G. Simpson (1870) and Augustus Waller (1870) of angina pectoris; Liston (1847), Morel Lavallée (1865), Gustav Simon (1876), Murchison (1879), Nikolaus Friedreich (1882), Hilton Fagge (1883) and Baelz (1913) of aortic aneurysm, and Wepfer (1695), the historian A. Hirsch (1894) and Heinecke (1901) of "calcification of arteries." Tuberculosis, also apparently one of the greatest enemies of the doctor himself, carried off Swammerdam (1680), Zinn (1759), J. G. C. von Siebold (1798), Bichat (1802), Robert Willan (1812), Bayle (1816), Mathew Baillie (1823), Laennec (1826), Canstatt (1850) and Lockhart Clarke (1880).

Van Helmont (1864) and Dupuytren (1835) died of pleurisy, and the physician-poet Mark Akenside (1770)—whose name Vierordt distorts into "Mark A. Kenside"—and Valleix (1885) of diphtheria. Gout numbered among its victims Scaliger (1558), Jerome Cardan (1596), Sydenham (1689), Linnaeus (1778), William Hunter (1783), Berzelius (1848), Corrigan (1880) and Cohnheim (1884). Smallpox killed Caspari (1828), Döllinger (1841), John Bostock (1841) and Henry Gray (1868); cancer, Lorenzo Bellini (1704), Sir Benjamin Brodie (1862), Mikulicz (1905) and Möbius (1907); septicemia, Spigelius (1625), Claude Perrault (1688), William Hewson (1774) and Kolletschka (1847); typhoid fever, Rush (1813), Spurzheim (1832), William Wallace (1838), Deiters (1863), Oppolzer (1871) and Meyer, the describer of adenoid vegetations, (1895); typhus fever, Reil (1813), John Syng Dorsey (1818) and G. Cornet (1915); dysentery, Thomas Hodgkin (1866), and erysipelas, K. W. Jacob (1858) and Moleschott (1893). Claude Bernard (1878) and Pasteur (1895) succumbed to uremic seizures; Neumeyer (1871) and Liebermeister (1901) to sarcoma of the kidney; Haller (1777) and Scarpa (1832) to cystitis; Riolan (1657), Rivinus (1723) and Portal (1832) to urinary calculus; Jobert de Lamballe

(1867), Theodor Simon (1874) and Karl Schroeder (1887) to brain disease; Bronssais (1838) to hemorrhagic colitis, and W. E. Horner (1853), Griesinger (1868), Middeldorpf (1868) and F. W. L. Bischoff (1882) to perforative typhlitis or appendicitis.

Wirsung (1643) and Delpech (1832) were assassinated; Desault (1795) may have been poisoned; Servetus (1553) was burned; J. von Jessen (1621) and Struensee (1722) were beheaded; Carpue (1846), C. Waller (1862), Bouvier (1877), Pagenstecher (1879), von Gudden (1886), drowned in the Starnberger Sea, while struggling with the insane monarch, Ludwig II of Bavaria, during his last moments), R. Carmichael (1887), Wernicke (1905) and Oscar Lassar (1907) met violent death by accident, and John Aitken (1790), Horace Wells (1848), Michaelis (1848), von Baerensprung (1864), Treitz (1872), Victor Hanot (1896), M. von Pettenkofer (1901) and perhaps Joseph Toynbee (1866) committed suicide. To the list of assassinations should be added Lehr's extensive martyrology of physicians and asylum attendants killed by insane patients.

Electrocardiography

The electrocardiograph is a rather expensive, recently invented instrument, requiring some skill in its use. This probably accounts for the fact that the great majority of medical men have no detailed knowledge either as to the instrument itself or as to its value as a diagnostic aid. A brief review of the subject will therefore be worth while.

The contraction of the muscular walls of the heart set up electrical currents known as action currents. When these currents are conducted from the patient to a sensitive string galvanometer (a silver thread approximately 1/25,000 inch in diameter suspended between the poles of a magnet) definite movements of the string result. These movements are photographed by a moving plate or film. The resulting picture is an electrocardiogram and, in reality, is a graphic portrayal of the cardiac action. Extensive experimental work by Einthoven, the inventor of the electrocardiograph, by Thomas Lewis and others, has demonstrated the significance of the various points in such a tracing and the alterations in this picture that occur in various pathologic conditions have become definitely established.

With the aid of the electrocardiograph it has been almost indisputably proved (Eyster and Meek, Experiments on the Origin and Propagation of the Impulse in the Heart, *Heart*, 1914, v, 119) that the impulse which causes the heart to beat arises in a specific bundle of muscle fibers in the roof of the right auricle, known as the sinus node. This impulse is conveyed to the various chambers of the heart by a distinct system of fibers. When other points in this system become more irritable than the sinus node, a contraction impulse may arise here, and an extra beat or so-called extrasystole results. Whether such an impulse originates in the auricle, in the right or left ventricle or in the junctional tissues between the auricles and ventricles may be determined with the electrocardiograph. The large group of cardiac irregularities caused by extrasystoles has thus been definitely classified. An irregular pulse is often a matter of great concern to both the patient and the physician, and the electrocardiograph is an essential aid in determining whether an irregularity is of grave import or whether it is an extrasystole and of little significance.

Examples of heart block give a characteristic tracing. Since an auricular contraction results in a definite wave followed in a short interval by a series of waves depicting the ventricular contraction, any disturbance between the number and regularity of the auricular and ventricular beats is graphically portrayed. If there is a complete blocking of the impulse in its passage from the auricle to the ventricle through the bundle of His the auricular waves in the tracing are much more numerous than the ventricular waves and have no relation to them. This is the result of the independent rhythm of the auricles and ventricles that is established in complete block. If the blocking is only partial every second or third auricular impulse gets through the bundle of His and is followed by a ventricular contraction.

The advent of the electrocardiograph has established a heretofore unknown type of heart irregularity, auricular fibrillation, and one that is probably more frequently encountered than any other. In this condition the auricular musculature is fibrillating and instead of 60 to 80 strong auricular contractions per minute there may be as many as 400 to 500 pseudocontractions. Few of these impulses get through the bundle of His and the result is a markedly irregular pulse. Such a tracing contains numerous small auricular waves bearing no relation to each other and only an occasional one followed by a ventricular systole. When auricular fibrillation is suspected on physical examination an electrocardiogram is an invaluable help in establishing the diagnosis.

Information concerning the myocardium as a whole is also furnished. Hypertrophy of the auricles or of the ventricles is represented by an increase in the height of the auricular or ventricular waves. In mitral stenosis an increase in the height of the auricular wave has often called attention to a lesion which has not been suspected on physical examination. Recently it has been possible to take tracings representative of the heart tones and thus murmurs and their relation to the cardiac cycle are accurately recorded.

Physicians and the Hall of Fame

The *British Medical Journal* thus comments on the tabulation by Mr. Pickering in *Science* of the votes at the three elections of the American Hall of Fame:

"Politicians head the list. Next come authors. It is significant of the value of popular judgment that while of eleven writers of fiction nine were elected, of ten authors who dealt with serious subjects, only three gained the *arbitrium popularis aurai*. Next come soldiers and sailors. Doctors hold a low position, but this is not surprising, as medicine is not a profession which leads to popular fame among Anglo-Saxon peoples. What is surprising is that in a country like America which swarms with inventors, and where the cult of the 'almighty dollar' is generally believed to be so prevalent, engineers and business men are nearly at the bottom of the list. 'Philanthropists' stand lowest of all. The list suggests some curious reflections as to the mentality of the American people, but it would be rash to draw any definite conclusion from the figures. The system of voting is probably accountable for the strangeness of the results, for till now the judges have been literary men who may be assumed to have been more familiar with the work of authors than with that of men whose activity was displayed in other fields. Even allowing for this, it is remarkable that among so practical a people fiction should hold the place of honor in literature; and it is hard, as Mr. Pickering says, 'to believe that there are . . . twelve authors more famous than any American missionary, physician, engineer, or business man.'"

Improvement in Milk Supply

The National Clean Milk Society of London is making an effort to raise the hygienic standard of milk and milk products sold in London, and to educate the public as to the importance of a clean and wholesome milk supply. According to A. E. Ingram, U. S. consul at Bradford, when the milk and dairies act of 1914 was passed an effort was made to have a provision inserted for certified milk such as is now produced in the United States. The provision failed of adoption. Efforts are also being made to have the scorecard system of dairy inspection adopted such as is used in the United States. The city of Bradford has already adopted the plan. The British Board of Agriculture is encouraging the formation of milk recording societies. It is said that heretofore the dairy men have not appreciated the value of milk records. Up to March, 1915, only sixteen societies have been formed throughout the country.

Medicolegal

Amount Physicians May Prescribe Under Harrison Antinarcotic Law

(United States vs. Friedman (U. S.), 224 Fed. R. 276)

The United States District Court, Western District of Tennessee, sustains a demurrer to, and quashes, an indictment that charged the defendant with having dispensed, distributed, and prescribed gum opium and powdered opium, the derivatives, compounds, and preparations thereof, to wit, morphin sulphate, heroin, and cocain, a derivative of coca leaves, without the dispensing, distribution, and prescription as aforesaid being in the course of his professional practice; that is to say, that he dispensed, distributed, and prescribed the aforesaid drugs in quantities more than was necessary to meet the immediate needs of a patient, and did not distribute, dispense, and prescribe the drugs in good faith and as a medicine. The court says that the indictment was drawn under Section 2 of the Act of Congress approved Dec. 17, 1914, known as the Harrison Antinarcotic Law. An attentive examination of the indictment disclosed that the offense with which the defendant was charged was dispensing, distributing, and prescribing the prohibited drugs in quantities more than was necessary to meet the needs of a patient, and that they were not distributed, dispensed, and prescribed in good faith and as a medicine. As the court understands Section 2 of the Act, the only thing required of a person, who shall give an order as provided in said section for the drugs mentioned in the act, is that he shall make or cause to be made, at the time of giving the order, a duplicate thereof, on a form issued by the commissioner of internal revenue, and in case of the acceptance of said order he shall preserve such duplicate for two years. The defendant was not indicted for failure to do either of these last-mentioned things. Subsection "a" of Section 2 provides that nothing contained in the section shall apply to physicians, dentists, or veterinary surgeons, registered under the act, who dispense or distribute any of the drugs in the course of their professional practice, provided that they shall keep a record of all of such drugs dispensed or distributed, showing the amount dispensed or distributed, the date, and the name and address of the patient to whom such drugs are dispensed or distributed, unless the physician shall administer them personally to the patient. But the defendant was not indicted for violation of subsection "a," but, as has been said, he was indicted for giving a prescription for said drugs in quantities more than was necessary, and not in good faith and as a medicine. The court fails to find in the act of Congress under examination any language making the doing of the things with which the defendant was charged a violation of law. In other words, there is no limit fixed to the amount of said drugs that a physician may prescribe, nor is there any duty imposed on him, other than to keep a record of all such drugs dispensed by him, and the name and address of the patient, except those to whom he may personally administer, and that he must preserve the records for a period of two years. For failure to do either of these things the defendant was not indicted. The result is the court holds good a demurrer to the effect that the acts of the defendant averred in the indictment are not prohibited by law, nor are they in violation of any law of the United States.

Constitutionality of the Harrison Antinarcotic Law

(United States vs. Brown (U. S.), 224 Fed. R. 135)

The United States District Court in the Western District of the State of Washington overrules a demurrer to an indictment charging the defendant with unlawfully having in his possession and under his control about 3 drams of "yen shee," a derivative and preparation of opium, he not having registered nor paid the special tax as required by the Act of Congress of December 17, 1914. The demurrer was filed on the ground that the indictment did not state facts sufficient to constitute an offense under any valid or constitutional law of the United States. It was contended that the support of the indictment, if any, must come from Section 8 of the act referred to, and that this section, which makes it unlawful for any person who has not registered and paid the special tax as provided by this act to have in his possession or under his control any opium or coca leaves or any compound, manufacture, salt, derivative or preparation thereof, is unconstitutional, in that it is an attempt on the part of Congress to encroach on the police power of the several states; that the only right Congress has to control the sale of a commodity, within the provisions of the Constitution, is (a) to regulate commerce; (b) the right of taxation; and neither of these rights is invoked by Section 8. But the court says it thinks it may assume, and will take judicial notice of the fact, that no opium is grown or produced in this country, and that the purpose of the act is to prohibit the importation of opium. The purpose of Congress being to prohibit the importation, manufacture, or sale of the drugs described, and by this act the drug having become an "outlaw" in the country, Congress has a right to trace its presence, and has the power to punish any person in whose possession this "outlawed" article may be found. The possession of such drug or control thereof is made presumptive evidence of the unlawful importation, manufacture, etc., as well as an obligation to pay the special tax provided by the act, and a failure to register and pay the tax as provided would be a fraud on the United States, in that it deprived the government of the revenues provided by the act. Congress, having the power to exclude the drug entirely from the United States, and the right to regulate its relation to interstate commerce, and to levy a tax, must be held to have the right to make it unlawful for any person who has not complied with the provisions of the act by registration or paying a tax, to have in his possession this "outlawed" article. The act must be construed as a whole, and force given to every part when this can be done.

Indictable Use by Physicians of Mails to Defraud

(United States vs. Baxter et al. (U. S.), 221 Fed. R. 473)

The United States District Court, Northern District of California, overrules a demurrer to an indictment for using the mails in furtherance of a scheme to defraud. The court says that the scheme, as set forth in the indictment, was that the defendants, as physicians, should by means of advertisements induce certain persons named in the indictment, and others to the grand jurors unknown, to communicate with them relative to real or supposed ailments. That the defendants should then, by means of letters and through the postoffice department, and irrespective of any symptoms communicated to them, and even in cases in which the symptoms indicated health, rather than disease, and without any real knowledge of the condition of the person so induced to communicate with them, state to such person that he was afflicted with a disease which the defendants could cure, and that they would furnish treatment for such disease for a certain sum of money, and by means of such letters would induce such person to send them money for the purpose of procuring medicine and treatments skilfully and properly designed and prepared for the cure of the disease with which such person was afflicted, or had been induced by them to believe himself afflicted, which money they would fraudulently convert to their own use. That in return for such money they should send to such person certain medicines of little or no value, and not medicine and treatment skilfully and properly designed and prepared for the cure of such person, the defendants having no real or proper knowledge of such person's condition, or whether he was diseased or not, or whether or not such purported medicine was capable of benefiting such person, as they well knew. It was contended on the demurrer to the indictment that for many reasons the foregoing scheme was not one to defraud within the meaning of Section 215 of the criminal code. But to this contention the court is unable to agree. When it is averred that a physician has devised a scheme to defraud, by stating to one who offers himself as a patient that such person is afflicted with a disease which the physician can cure, and this irrespective of the symptoms, and whether or not the symptoms indicate health rather than disease, and without any real knowledge of the condition of such person, and by such statement should cause and induce such person to send him money, for which he would send in return medicine of little or no value, and not medicine skilfully and properly designed and prepared for the cure of the disease with which such person was afflicted, or had been induced by such physician to believe that he was afflicted, the court thinks it clearly appears that the physician was engaged in one of the most reprehensible schemes to defraud of which the law can take cognizance. It may, indeed, be quite true that medicine is not an exact science, and that there is a wide divergence of opinion, even among reputable physicians, as to what is the proper method of treatment for any particular disease. But this fact is beside the mark here. All such treatments contemplate at least good faith on the part of the physician, and are not based on a deliberate design on his part to procure money from a person who, so far as the physician knows or has reason to believe, is in sound health, by stating to him that he is afflicted with a disease; and this is true, whether resort be had to the use of the mails or not. The design as alleged may not be easily proved; but it is a design to defraud, and the indictment is sufficient.

A Limited Partnership Between Physicians and Their Liability for Malpractice

(Pier vs. Cauley et al. (Neb.), 152 N. W. R. 298)

The Supreme Court of Nebraska, in reversing a judgment rendered in favor of the defendants, two physicians sued for malpractice, and remanding the cause for further proceedings, holds good, as against a joint demurrer, a petition which charges concurrent and inseparable acts of negligence, which result in injury to the patient, against two physicians charged with the care and treatment of the patient. The court says that the plaintiff alleged that the defendants, Drs. Cauley and Allenberger, one of whom practiced at one place, and the other at another, had an arrangement with each other whereby, in cases in which Dr. Cauley was called in his professional capacity to attend and treat a patient for a wound or physical injury of any kind, and particularly when he was called in a case which needed or required a surgical operation or treatment, he was to call Dr. Allenberger in consultation and to aid and cooperate with him in such treatment and operation, and was to charge his patient for the services of each of them. That the plaintiff broke her leg below the knee in such a manner that the bones protruded from the wound and dirt and foreign substances were admitted therein. That Dr. Cauley was called to treat the case, but negligently omitted to remove from the wound the dirt and foreign substances, and negligently failed properly to treat the injury or reset the broken bones, in addition to which he urged the plaintiff's parents to cause her removal to a hospital in the city where Dr. Allenberger was located, and where Dr. Allenberger was, pursuant to the arrangement before mentioned, called by Dr. Cauley to come and aid him in the treatment of the case, and that Dr. Allenberger, with the knowledge and consent of Dr. Cauley, and pursuant to said arrangement with him, continued unskilfully and negligently to treat the plaintiff for said injury for a period of over nine weeks. That, as soon as the plaintiff's parents learned her true condition and of the alleged negligent and incompetent treatment, they took her to another surgeon, who amputated her leg. the amputation being necessary to save her life and made necessary by the "negligence, unskilfulness, and carelessness of said defendant." The defendants filed a joint demurrer to the plaintiff's petition on the grounds that the several causes of action therein stated were improperly joined, and that there was a misjoinder and a defect of parties defendant. The demurrer in effect admitted the truth of all the allegations of the petition, one of which was with regard to the arrangement or agreement between the defendants, before mentioned. The effect of this agreement was to create a limited partnership. No separate cause of action was necessarily stated against Dr. Cauley, because the acts of negligence charged were continuing acts, beginning with his first failure to cleanse the wound, and extending throughout the time that the patient was under the care of himself and his special partner, Dr. Allenberger. Counsel for the defendants cited a number of authorities in support of their contention that the petition stated two causes of action, one for the wrongful acts and omissions of Dr. Cauley while acting alone, and another for the acts and omissions of the two physicians while acting jointly; but in the cases cited there was no concerted action between the different defendants, but each of the wrongdoers acted independently of all others, although the effect of what they did merged and produced the injury. If the defendants acted separately, each independently of the other, there being no concert of action between the two, there would be no joint liability; but if their acts were concurrent and inseparable, and, taken together, produced the injury alleged, they were jointly liable therefor.

Standard for Measuring the Nuisance Qualities of a Noise

(Wahrer vs. Aldrich (Wis.), 152 N. W. R. 456)

The Supreme Court of Wisconsin affirms a judgment holding that a proprietor of a hotel was not entitled to have the operation of a neighboring roller skating rink permanently enjoined, but only later than 10 o'clock at night. The court says that, as would be expected in a case of this kind, there was a wide range in the testimony regarding the volume of noise made by the rink. Some described it as very loud and annoying and others as nothing out of the ordinary. All practically agreed that the noise made by the skating was that of a rather loud rumbling noise—much like that of a train passing over a bridge. Some found the music pleasant, some unpleasant, and on others it seemed to have made no particular impression. There was medical testimony to the effect that the noise was not of a kind physically to annoy persons of ordinary sensibilities. The court thinks that the evidence supported a finding of fact to the effect that the operation of the rink, as conducted, was not physically annoying to any of the permanent residents, of ordinary sensibilities, in the neighborhood. The standard for measuring the nuisance qualities of the noise was its effect on a person of ordinary sensibilities. It was to be gaged neither by a neurotic nor a phlegmatic temperament. To constitute a nuisance, it must be physically annoying; it was not sufficient for it to offend mere taste or what was ideally desirable. An actual effect of discomfort must be produced by it on the average nervous organization before courts would interfere.

Examination by Physicians for Defense After Exhibition to Jury

(Houston & T. C. R. Co. vs. Bukowsky (Tex.), 175 S. W. R. 477)

The Court of Civil Appeals of Texas, in affirming a judgment in favor of the defendant railroad company, in this personal injury case, holds that there was no error in refusing to permit two physicians to examine the plaintiff's foot outside of the courtroom, and not in the presence of the jury, with the view of determining whether or not he was in fact injured as claimed by him, and thereafter testifying as to the result of their examination, which, it was contended, would have disclosed that the plaintiff was malingering, and that his foot was not in fact injured. The court says that it was not shown that a full examination could not have been made by the physicians in the courtroom and in the presence of the jury. Where the plaintiff voluntarily submits to a personal examination in the presence of the jury by physicians of his own selection, who testify with reference thereto, then it would be error to refuse to permit the opposite side to examine him by its physicians for the purpose of controverting the result of the examination as testified to by his own witnesses; and for this purpose, if it is made to appear that such examination cannot be made by the opposing witnesses in the presence of the jury, it would be the duty of the court to permit them to make such examination apart from the jury. This case, however, did not come within this rule.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS

Twenty-Eighth Annual Meeting held at Pittsburgh, Sept. 14-16, 1915

The President, Dr. Charles L. Bonifield, Cincinnati, in the Chair.

Local Anesthesia in Herniotomy

Dr. J. H. Jacobson, Toledo, Ohio: Among 124 operations done by me there have been no deaths. My experience with this method has convinced me that whenever possible, such operations should be performed under local anesthesia. The only exception to this rule should be in herniotomy in children and when the operation must be performed in uncontrollable nervous adults. In only three of the operations was it necessary to complete the operation with a slight amount of ether. These were among the earlier operations.

I have never observed the slightest toxic effect from the use of the 0.5 per cent. novocain and epinephrin solutions which I have employed for these operations.

DISCUSSION

Dr. John W. Keefe, Providence, R. I.: My experience is in accord with that of the essayist. Most of the operations for inguinal hernia can and should be done under local anesthesia.

Dr. Albert Vander Veer, Albany, N. Y.: A hernia operation should not be undertaken in children under local anesthesia. A general anesthetic is best for that purpose.

Dr. William H. Humiston, Cleveland: In following an exclusive method of anesthesia, one is inclined to make every case submit to that form of anesthesia, and in my early work I soon found out that this is poor judgment. We must select our cases.

Case of Intestinal Obstruction and Volvulus

Dr. Rufus B. Hall, Cincinnati: This case of intestinal obstruction and volvulus was caused by a large gallstone. The profession generally does not regard gallstones in which the patient is not a great sufferer as a surgical condition. These patients are treated by physicians, with very indefinite results, so far as any permanent relief is concerned, the symptoms being variously described by such vague terms as indigestion, neuralgia, gastritis, etc. They are surgical cases and I recommend exploratory operation in all those chronic cases in which there is a clear past history of one or more acute attacks. In those cases in which the stone, through ulceration, passes into the bowel, the patient is subjected to great danger, even if he does survive. When intestinal obstruction occurs, it is so many years after the acute attack that the real cause is not recognized until revealed at the operation or necropsy. The long history of gallstone is ignored or forgotten.

DISCUSSION

Dr. Hugo O. Pantzer, Indianapolis: The first case of this kind was reported by Dr. Elsner, of Rochester, N. Y., about twenty years ago. There was a history of gallbladder trouble attended by attacks of acute obstruction. In each of the attacks, a different part of the abdomen appeared to be the seat of obstruction. Finally, the stone was passed per rectum.

Dr. Gordon K. Dickinson, Jersey City, N. J.: If 30 per cent. is our accurate diagnostic average in the abdomen, then operation should be done promptly, and more on suspicion than on an accurate diagnosis, more on opinion that something is wrong than to wait until we feel that something is positively and surgically bad. In going over my cases I find that death in many of them was due to dilatation of the right side of the heart, which comes on quickly after an abdominal operation, partly due to the anesthetic, and partly due to the condition of the heart before operation.

Dr. J. Henry Carstens, Detroit, Mich.: We do not perform these operations early enough. If we can make a diagnosis and resort to an exploratory operation promptly, we would not have so many of these cases terminate fatally.

Dr. Magnus A. Tate, Cincinnati: Five years ago I saw a woman, 60 years of age, who had been complaining of progressive pain and tenderness for a number of years. One day she was taken with severe continuous vomiting, and the abdomen was distended. She refused to undergo an operation. Later she was operated on, and a stone, 2½ inches in size, was found in the intestine, about 6 inches from the gallbladder. The intestine was gangrenous and ready to burst. In making the resection a portion of the contents escaped into the abdominal cavity. The patient went into a state of collapse and died about three hours after the operation.

Dr. John F. Erdmann, New York: I have had five cases of intestinal obstruction from gallstone in the past ten years, and of this number four patients died. Strange to say, the recovery was in a woman 72 years of age on whom I did an enterostomy and appendectomy. She also had a large tumor of the right ovary which was mistaken for an appendicitis.

Dr. Herman E. Hayd, Buffalo: I recall a patient, a woman, 79 years of age, who had practically no symptoms. So far as the passage of a stone is concerned, she never had an attack of violent pain, and yet the stone found was as large as a small hen's egg. I was called to see her when she was having fecal vomiting. She vomited for two days. I operated, removed the stone, and she lived five days after the operation. There was no history of ulceration or of an inflammatory attack. The stone was found in the bowel and the symptoms were those of intestinal obstruction.

Dr. Albert Vander Veer, Albany, N. Y.: A patient whom I had attended some fifteen years previously was taken very ill and had what we supposed was an acute jaundice. He recovered from this attack and lived fifteen years afterward in good health. At the time of death, I was allowed to make a necropsy. We suspected he had some malignant disease of the intestinal tract. I found a direct communication between the neck of the gallbladder and the beginning of the transverse colon. I believe this man in his previous illness had passed through a form of sickness that had resulted in relieving the gallbladder of gallstones, and they had passed out through the large intestine. The fistulous tract gave him no great inconvenience.

Dr. Charles L. Ill, Newark, N. J.: In forty patients operated on by my brother and myself we found three large gallstones in the small intestine. In one case we found a mass between the small intestine and the gallbladder. Three large gallstones were passed through ulceration into the intestine, caused obstruction, and killed the patients.

Dr. D. Todd Gilliam, Columbus, Ohio: When we speak of being unable to find a gallstone or gallstones near the lower part of the ileum, there is reason for it. The upper part of the intestinal canal is larger in caliber than the lower, and a gallstone will pass down pretty well toward the entrance of the ileocecal region before it becomes arrested, and the lower part of the ileum is less distensible than the upper part. Whenever we find great distention of the abdomen along with obstruction, it should always remind us of gallstones.

Dr. John Norval Bell, Detroit: A woman, 67 years of age who had never had any pain, but simply heaviness and fulness, had a palpable tumor of good size. It was hard to determine its nature. On opening the abdomen I found it was a large thickened gallbladder full of stones.

Dr. William Edward Darnall, Atlantic City, N. J.: I recall a patient I saw a year or two ago on whom I operated after the diagnosis of appendicitis with all of its symptoms, and I found a small collection of pus and in it a stone (undoubtedly an enterolith) about the size of a goose egg. It was about one-eighth of an inch thick, with a hard shell of calcium salts. Such accumulations of bile salts under some circumstances go on to form a full gallstone.

Cholecystectomy Versus Cholecystostomy

DR. L. W. SWOPE, Pittsburgh: No absolute rule can be laid down to guide one in determining when cholecystectomy is preferable to cholecystostomy, yet there should be some way of ascertaining why the percentage of cures is higher after removal of the gallbladder than after draining. From the former cases in the patients who survived operation and answered my inquiries I get a report of 96.8 per cent. cures, and the remainder suffer from symptoms probably indicating associated gastric or pancreatic disease. On the other hand, in cholecystostomy, there were only 74.8 per cent. of cures, the remainder being no better and many of them worse than before operation. In considering the latter it is, of course, true that in many of them the disease was so advanced and adhesions so extensive that removal of the gallbladder was out of the question because of the high mortality in such cases. There are still a large number in which it seems to be reasonable to suppose that better permanent results would have been obtained by removal of the gallbladder instead of drainage. This argument receives verification in the results obtained in the two-stage operation where for some reason we decided to drain the gallbladder at the first operation and remove it from four to eight weeks later. The dangers of cholecystectomy include the possibility of injuring the ducts, vessels and surrounding viscera from the manipulations necessary to free the adhesions. When adhesions are so extensive that the removal of the gallbladder would be attended with marked traumatism and leave large areas of raw surfaces to be covered, then because the primary mortality is so high and the hope that subsequent complications will not arise is so uncertain, I believe better results are obtained by drainage of the gallbladder. While a diseased gallbladder, like a diseased appendix, should always be removed when possible, still there are exceptions. Because primary removal of the gallbladder opens up so many tracts for the possible extension of infection, and because experience has shown that occasionally a patient does die from acute sepsis in infections of this kind, I am convinced that such a gallbladder should be drained with as little manipulation as possible. Then at the end of from four to eight weeks, if recovery is comparatively complete, the gallbladder should be removed, as these patients are the ones who are left with a chronic infection which advances so insidiously that years may elapse before a return of symptoms, but when they do return the involvement of the upper abdomen is frequently too extensive to permit complete removal and ultimate cure. These cases also offer favorable sites for subsequent malignant degeneration. In advocating cholecystostomy in infective cases I do not include hydrops and chronic empyema of the gallbladder in a quiescent state, as cholecystectomy is safer when the infection has ceased to be active.

DISCUSSION

DR. JOHN F. ERDMANN, New York: As to cholecystectomy versus cholecystostomy, activity, efficiency and morbidity are the things we should consider in order to reduce the mortality to the lowest point. Anything that would increase efficiency must of necessity decrease morbidity, and cholecystectomy without any question limits morbidity and increases efficiency. As a result of my statistics I have been doing cholecystectomy practically in every case. There are some cases, however, in which we must do cholecystostomy.

DR. C. S. FOSTER, Pittsburgh: There is an indication for removing gallbladders that cause no symptoms. For instance, if we suspect the ducts to be enlarged and the glands enlarged down along the ducts, independently of pancreatic disease or of involvement of the viscera of the stomach, such a gallbladder is infected and ought to be taken out.

DR. JOHN W. KEEFE, Providence, R. I.: We ought not to operate during the acute stage of inflammation in gallbladder disease. Occasionally, we will have perforation and gangrene, and there will be a few cases in which it is necessary to operate during that period, but if one can keep away from operation and wait until convalescence is established, he will meet with greater success when he does operate.

DR. FRANCIS REDER, St. Louis, Mo.: With regard to feeding a patient deprived of bile salts on ox-gall, if you are reasonably certain that the patient's bile is in a normal condition you can feed that patient with his own bile by simply making him drink it.

Unusual Contents (Kidney) of Inguinal Hernia

DR. CHARLES W. MOOTS, Toledo, Ohio: A woman, aged 38, had never suffered any illness necessitating her remaining in bed. About nine years ago she noticed a lump the size of a hickory nut in the region of the right internal abdominal ring. It remained about the same for eight years, when it came lower and appeared to double in size. At this time it also became very painful. Operation was performed Aug. 22, 1914, under local anesthesia. I made the usual skin incision and then found that the mass could not be pushed upward into the inguinal canal as it was adherent to the labium majus. An elliptical portion of the labium majus was excised in order to free the mass, which now gave me the impression that I was dealing with a kidney. However, it being almost beyond the point of identification, an opening was made in the peritoneum, when the right kidney space was explored and found empty. The left kidney was normal in size, location and consistence. A nephrectomy of the useless right kidney was done and the inguinal canal closed in the usual manner. The kidney was composed of a mass of small cysts about one-half inch in diameter.

A Prognostic Sign in Acute Suppurative Peritonitis

DR. HUGO O. PANTZER, Indianapolis: The presence within the abdomen in cases of peritonitis of a free or encaps lated serous or seropurulent fluid, which is practically wit out odor, by the side of encapsulated foul material, ind cates a strong systemic defensive activity of distinct prog nostic value. A male baby, 6 months of age, had becom acutely ill and at once revealed the characteristic signs an symptoms of an acute general peritonitis of probable appendi ceal origin. The temperature was 104 F., pulse feebl and 170 to the minute. At operation there was foun much free fluid within the abdomen, cloudy with pus, b odorless; and about the ileocecal coil were extensive adhe sions enclosing an abscess containing about 45 c.c. of cream and extremely foul pus, and the gangrenous appendix. Th case seemed utterly hopeless, yet it turned straightway t recovery. With three drainage tubes within the abdome the very next day the child was found cooing merrily an taking its mother's milk, and from that time on it bega to recover speedily.

Abnormality of Sigmoid

DR. BUDD VAN SWERINGEN, Fort Wayne, Ind.: A woma 37 years of age, had suffered from childhood with consti pation. Palpation of the abdomen elicited tenderness an tumefaction in both flanks. By the vagina a mass in th left side was felt to be very hard and larger than one on th right. The abdomen was opened. The omentum was firml adherent on the left side; a tubo-ovarian abscess on th right side was removed, also the appendix. In enucleat ing the left tube and ovary, which were very intimatel adherent to the sigmoid, there was uncovered a cylindrica structure about 6 inches long, apparently coming out of th side of the sigmoid and entering the lateral aspect of the rectum. After freeing it, it was thought to be a diverticulu open at one or both ends. As the main channel of the bowe was thought to be still uncovered the diverticulum wa ligated at the sigmoid and rectal attachments and removed Preliminary to closure of the abdomen water was run int the rectum. The sigmoid and descending colon could n be filled. We had evidently destroyed the only passage between the rectum and colon. We therefore anastomo the rectum and sigmoid by the Noble method at the site the former channel. The woman made a satisfactor prolonged convalescence, and went home with a fecal fistula for which she was successfully operated May 11, 1915.

Mesenteric Thrombosis; Report of Two Cases

Dr. William Edgar Darnall, Atlantic City, N. J.: Infection plays a decidedly more important part in the etiology of mesenteric thromboses than we have thought in the past. Cases of acute mesenteric thrombosis are the result largely of some focus of infection, such as appendicitis, gallbladder infection, ulceration of the intestine or even of metastasis from a more distant focus. The superior mesenteric artery is most often the seat of the trouble. Any other treatment than operative need not be considered. Resection of the involved intestine is usually done, but many patients have been lost who possibly might have recovered if the anastomosis had been delayed and a secondary operation done later. The reason for this is that one cannot be certain that the gangrene has reached its limit and will not extend farther and that the complete operation is apt to involve more time and trauma than the patient can stand. These patients are usually in bad condition when they come for operation. It is therefore better that the gangrenous portion of the intestine should be brought well out of the incision, leaving full liberal margins at both ends. The intestine should be resected and its ends sewed into the wound, which is walled off with gauze. With both ends of the intestine thus opened, distention may be relieved and signs of further extension of the gangrenous process watched. At a later day, if the patient survives, the fistula may be closed and an anastomosis done.

President's Address; Some Comments on Present Day Tendencies in Gynecologic and Obstetric Practice

Dr. Charles L. Bonifield, Cincinnati: One method of diagnosis strongly recommended by some operators in recent years seems to me to be seldom needed. I refer to the opening of the uterus. The greater one's familiarity with intra-abdominal conditions the less frequently he finds it necessary to do an exploratory abdominal section. Hysterotomy will find more frequent employment in the hands of the general surgeon who has broadened his field to include gynecology than in the hands of a gynecologist who has studied at the feet of a master of the art. It is from the laboratory rather than from the operating room that further success in dealing with cancer is to be expected. The importance of early diagnosis and operation is thoroughly recognized by the surgeon, if not by the laity, and the radical and painstaking operations now performed have merely reached the limit as to thoroughness. Further experience with radium has pretty well demonstrated the position it should occupy in cancer therapy. The surgical treatment of uterine fibroids in the hands of an operator skilled in pelvic surgery is now so successful and satisfactory that any other form of treatment will have to show brilliant results to supplant it. As to the administration of anesthetics, I prefer my anesthetics to be given by some one whose knowledge of anatomy, physiology and therapeutics enables him to meet emergencies that may arise without much direction or supervision on my part. The professional anesthetist is a useful member of the profession, but naturally likes to magnify his calling, so he provides himself with expensive and complicated apparatus that makes the operating room look like the inside of a submarine. I do not claim that nitrous oxid is not a useful agent, and that there are cases in which it is preferable to either ether or chloroform, but I do claim that it has not been proved that gas is safer than ether as the routine anesthetic for major surgical operations.

Luteum Extract in the Treatment of Menstrual Disorders

Dr. Adam P. Leighton, Jr., Portland, Me.: There are cases of dysmenorrhea in which the main causal factor is deficient action of the natural corpus luteum. I am not carried away with the idea that the therapy of corpus luteum is a cure-all in any sense of the word. On the other hand, the cases which may be traced to ovarian deficiency are probably in the distinct minority. One must not allow himself to be so impressed with the etiologic value of some one factor in the cause of disease that he forgets or becomes indifferent to others of equal importance. Surgery is necessarily indicated in those cases in which we find pelvic pathologic conditions or anatomic abnormalities present, which we are wont to consider as probable causes of this disorder. There are some serious drawbacks to the use of corpus luteum. It generally must be used routinely or continuously to obtain and maintain results. Its action is not immediate, it is cumulative, and for that reason patients and we ourselves too often discard its use after a short trial, if it has been unproductive of good results. From 15 to 30 grains a day, seldom more, is sufficient in any case. Its prolonged administration has not brought about any untoward symptoms, with the possible exception of slight gastric disturbance in one or two instances. The subject of organotherapy, in its present experimental state, is rather involved and indefinite, and while it is sometimes difficult to recognize and identify cases which would be benefited by corpus luteum, yet when there is a possibility of ovarian deficiency being an etiologic factor in any gynecologic disorder, we owe it to the patient to make use of this remedial agency, for its value is well determined.

Present Status of Twilight Sleep in Obsterics

Dr. A. J. Rongy, New York: Judging from my experience extending over a period of fifteen months, and covering a series of over 350 cases, I feel that the value of the treatment and its acceptance, as a recognized therapeutic measure, will depend on our interpretation of the physiologic processes which are produced by these drugs. If we accept the theory that the semiconsciousness induced prevents the actual experience of pain, although apparently present in all its clinical phases, then labor must be considered painless, and therefore to refuse to adopt it would be a failure on our part to carry out the trust reposed within us. On the other hand, if the mental state induced does not actually prevent the sensation of pain and the patient is actually suffering, even though it be modified, then the value of this method will devolve on the degree of pain, diminution or analgesia, and not on the lack of recollection of pain or amnesia. I find it difficult to reconcile the fact that a patient, displaying all clinical evidences of pain, such as crying and groaning, as is observed in these patients, does not actually experience it. However, I am fully convinced that pain, in a goodly proportion of cases, is influenced to a degree that would warrant its adoption in selected cases, more particularly in the primiparas of the highly emotional type and in multiparas in whom we anticipate long and tedious labors.

The Teaching of Obstetrics

Dr. Charles Edward Ziegler, Pittsburgh: I would not overemphasize the importance of didactic teaching in obstetrics. It is basic and indispensable. It must in part precede and in part accompany clinical teaching, but can never take its place, as has too long been attempted. In times past obstetrics was taught very largely didactically and in certain quarters this is still the case. Even at present in all but a few medical schools in this country, the clinical teaching and practical experience given undergraduate students in obstetrics are wofully deficient. Both the teaching and practice of obstetrics are generally regarded as the poorest of all the clinical branches of medicine. There must be a reason for this. The lay public will continue to regard with indifference all pleas for the improvement in the teaching of the practice of obstetrics so long as more than 50 per cent. of confinements are in the hands of ignorant, nonmedical persons, who, as a class, are regarded as capable of doing the work satisfactorily, even by physicians, among whom are certain well-known professors of obstetrics. The teaching of the clinical or practical side of obstetrics can be accomplished satisfactorily only through the medium of suitably equipped and properly conducted hospitals and dispensaries. Such hospitals and dispensaries should be teaching and research institutions in the fullest and broadest sense of the terms, with a large amount of obstetric material freely and constantly available for the purpose. The teaching staff, and there should be no other, should consist of full-time workers only, who should be paid salaries sufficiently large to make them independent of all other work. To become a thoroughly trained obstetrician, the graduate student must spend a number of years as assistant and teacher in maternity hospital and dispensary services of the type described. The major part of undergraduate instruction should be given by graduate students for this very purpose. The teaching helps them immeasurably. It gives them assurance, makes them alert, teaches them the invaluable art of expression, and develops clean-cut ideals and thoroughgoing, accurate procedure. Laboratory studies and research should constitute an indispensable part of all graduate study in obstetrics, not alone for the knowledge which the student acquires and for what he adds to the knowledge of the subject, but most especially because of the habit of investigation acquired thereby, which will make him fruitful in research later and prevent him the more certainly from degenerating into a mere money maker.

The Combined Operation for the Interruption of Pregnancy and Sterilization

Dr. Palmer Findley, Omaha: The combination of abdominal hysterectomy and resection of the fallopian tubes is the procedure of choice in all cases not previously infected. The removal of the ovum through an abdominal incision should be reserved for those cases in which permanent sterilization is desired. No other method is so free from the dangers of sepsis, retained secundines, perforation of the uterus and excessive loss of blood. In point of safety, expediency and efficiency, the procedure will appeal to all abdominal surgeons.

Surgical Operations During the Pregnant State

Dr. Francis Reder, St. Louis: A woman expecting to become pregnant should be thoroughy examined for any physical defect that might be found. Such a defect should be corrected, if possible, before pregnancy takes place. No operation that can be deferred should be performed on a pregnant woman. Any operation that will contribute to the safety of a pregnant woman should be performed without hesitancy.

Menstrual Statistics Based on a Study of 4,500 Menstrual Histories

Dr. K. I. Sanes, Pittsburgh: Seventy-five per cent. of women menstruated regularly and 25 per cent. irregularly. The most common regular type met with was that of twenty-eight days, which constituted 72 per cent. of this type. The thirty-day type followed next in frequency with only 3.8 per cent. and the twenty-one-day with 3.3 per cent., etc. In some of the thirty-one-day type the menstrual flow appeared monthly on the same date independent of the number of days in the month. The most common irregular types were from three to four weeks, then from four to five weeks, two to three weeks, five to six weeks, etc. The most common ages of onset in order of their frequency were 15, 12, 16. The age of onset did not show any relation to regularity or irregularity of menstruation. The earliest age of onset in our series was 9 years and the latest 24 years. The most common duration of menstrual flow was three days, then four or five days, three or four days, five days, seven days and four days. The irregular type of menstruation showed a larger percentage of long durations and smaller percentage of shorter durations than the regular type. The quantity of flow in 45 per cent. of women was normal, in 17 per cent. scant and in 37 per cent. profuse. Irregular patients showed a higher percentage of profuse flow than the regular ones. Hyperthyroidism cases showed a high percentage of profuse menstrual flow (65 per cent.). Clots were very frequently found in menstrual flow and we did not find them to be influenced by menstrual irregularity. Forty-seven and four-tenths per cent. of women suffered from dysmenorrhea (if the term dysmenorrhea is to convey the idea of discomfort). In retrodisplacements the percentage was found to be 50.4 per cent. In 50 per cent. of the dysmenorrhea cases the symptoms appeared during the flow, in 29 per cent. before, in 17 per cent. before and after, and in the rest after the flow or during and after. Most frequently the dysmenorrhea appeared the day before the flow, then the first day of the flow, then two days during, two days before, one day before and two days during, then three days before, and seven days before. Improvement in menstruation was frequently noticed with advance of menstrual life, after marriage and after childbirths, menstrual periods becoming more regular and the dysmenorrhea improving or disappearing entirely. The most common ages of menopause in order of their frequency were given as 50, 46, 48, 47, 51, 49, 44, 45, 52. The length of menstrual life was most commonly given as thirty-seven years, then thirty-five and thirty-three. Sixty-eight per cent. reported a menstrual life of thirty years or more. The very early and very late ages of puberty showed a rather early menopause.

Spinal Anesthesia in Gynecologic Operations

Dr. R. R. Huggins, Pittsburgh: After an experience with spinal anesthesia covering a period of two years I am convinced that it is of great value and that it will eventually find a high place among the methods of anesthesia, particularly for surgical procedures in the lower abdomen and pelvic cavity. The time is not here, however, when it can be used indiscriminately and by those who are not familiar with the contraindications. It is highly important to know when not to use it. A keen appreciation of its dangers and the unfortunate sequelae which have thus far caused considerable prejudice against the method will enable us to avoid its use in certain instances in which they are liable to occur.

29 *Treatment of Cystinuria; Report of Case. W. G. Smillie, Boston.

17. **Auriculoventricular Dissociation.**—As an occasional result of digitalis administration, there develops, says Christian, a cardiac disturbance consisting of variations in the form of succeeding ventricular complexes. Of the cases, one reported by Cohn, one by Oppenheimer and Williams and four by Christian, all except possibly one of the author's cases showed auriculoventricular dissociation. In one case the curve obtained did not justify any statement as to auricular activity; there may have been a regular rate in the auricles with auriculoventricular dissociation. All cases were of the type of chronic myocarditis without any marked signs of valve lesions.

18. **Inactivation of Pepsin by Sodium Chlorid.**—Hamburger summarizes his paper as follows: Sodium chlorid will prevent pepsin in aqueous solution from digesting protein. The inhibition of pepsin by sodium chlorid, together with the ability of animal serum to deviate pepsin (described in an earlier paper), is responsible for most, if not all, of the published accounts of antipepsin. The inhibition of pepsin by sodium chlorid is permanent, the inactivated ferment failing of reactivation by the subsequent addition of hydrochloric acid. The inactivation may be prevented, however, by dissolving the ferment in dilute hydrochloric acid. Neutralization of pepsin dissolved in hydrochloric acid alone (without the addition of sodium chlorid) inhibits the ferment by the sodium chlorid formed from union of alkali and acid, acting in a neutral solution. Complete neutralization of the gastric juice causes similar pepsin inactivation. The inactivation of pepsin by complete and continuous neutralization of gastric juice is indicated in the treatment of various diseases of the stomach in which temporary inhibition of peptic digestion is desired. This is particularly true in the prevention and cure of chronic gastric ulcer. By the use of certain foods, methods and time of feeding, and various alkaline substances, complete and continuous neutralization can be obtained.

19. **Endemic Typhus.**—Foster's observations are based on a study of twenty-three cases occurring among Filipinos. The first case was erroneously diagnosed as malaria. Tentative clinical diagnoses of typhus were made by elimination; but, in the absence of confirmatory laboratory evidence, the first positive diagnosis was not made until Oct. 12, 1914. The disease observed here corresponds to the acute infectious disease described by Brill, but the period of incubation appeared longer, the average leukocyte count was less and marked nervous manifestations—absent in Brill's cases—were not uncommon in Foster's cases. The onset was characterized by chill in twenty-one cases, headache in nineteen and by vomiting in six. Lumbar pain and pains in the extremities occurred in eight cases and vertigo was recorded once. In two of the cases the onset was gradual and fever was the first symptom noted. There was intense pain in the chest in one case at the onset, probably due to pulmonary congestion. The facies at the onset was that of intense congestion. The expression in some cases was anxious and in others dull and stupid. The color remained good until the crisis, after which pallor was evident for a variable time and the patient exhibited a "washed out" appearance.

The temperature rose rapidly during the stage of invasion, reaching the fastigium on the second to the sixth day. The average fastigium in twenty-one cases was 103.5 F., the lowest 102 F. and the highest 104.6 F. The fastigium was reached on the third or fourth day in 50 per cent. of the cases. The eruption occurred in sixteen cases, was absent in two cases and in the remaining five cases was either absent or overlooked. It appeared on the fifth day in two thirds of the cases but in isolated cases it was observed as early as the fourth day and as late as the eighth day. It appeared first on the abdomen and chest and developing rapidly and not in crops, had extended to the back, shoulders, arms, hands, legs and feet and in two cases to the face, within twenty-four hours. The lesions were discrete, slightly raised, rose red to dark red, irregular in outline and measured from 2 to 8 mm. in diameter. In the average case the spots were much more profuse than the rose spots of typhoid and less numerous than the lesions in the average case of measles. The eruption faded rapidly with the crisis and had disappeared by the tenth day. Desquamation did not occur.

The blood showed certain constant changes. The leukocyte count, in sixteen cases, varied from 4,000 to 18,000, the average count being 7,865. Differential leukocyte counts showed a rather consistent increase in the percentage of large mononuclear cells, with a corresponding decrease in the number of polymorphonuclears. Eosinophils were not present in appreciable numbers during the febrile period. Blood cultures in fifteen cases gave negative results. The pulse exhibited no characteristic features. The heart showed no variations from the normal except in one case. A soft blowing systolic murmur was audible in this case following the crisis. Anorexia developed early and persisted throughout the febrile period. Epistaxis, so constant a feature in typhoid, occurred but twice. Signs referable to the nervous system were common, and it appeared to stand the brunt of the infection. Retention of urine occurred rather persistently in one case, necessitating frequent catheterization. Polyuria was an almost invariable concomitant of the crisis. A relapse, intercurrent in character, occurred in one case. One death, due to acute ulcerative endocarditis following the crisis, occurred in the series of twenty-three cases, establishing a death rate of 4.34 per cent.

20. **Infantile Tetany.**—Fletcher holds that clinical observation would not warrant the conclusion that calcium changes alone account for the nerve irritability in tetany, but would seem to support the hypothesis that the tetany results from a disturbance of the concentration equilibrium of the salts. Such salt changes are probably associated with gastro-intestinal disturbances and decreased activity of the kidney, and, as improvement in the function of these two systems occurs, restoration of the normal salt equilibrium ensues. Treatment, accordingly, from these indications should aim at restoring a normal digestion and increasing the activity of the kidney.

21. **Hydrogen-Ion Concentration of Blood.**—The indicator method of determining H-ion concentration is made applicable to blood and serum by the authors by utilization of dialysis through a collodion membrane, which excludes the disturbing influences of color and of proteins. The method is simple, accurate, rapid and well adapted for clinical use. The technic consists of dialyzing 3 c.c. of blood or serum at room temperature against 3 c.c. of 0.8 per cent. salt solution for five minutes, adding an indicator and comparing with colored standard phosphate mixtures of known H-ion concentration. Phenolsulphonephthalein is employed as the indicator in this method. It is found to exhibit easily distinguishable variations in quality of color, with minute differences in H-ion concentration between the limits pH6.4 and pH8.4. Oxalated blood from normal individuals gives a dialysate with a pH varying from 7.4 to 7.6, while that of serum ranges from 7.6 to 7.8. Variations from these figures toward the acid side were encountered only in conditions which clinically, and from the standpoint of the laboratory findings, evidenced an acidosis. In a small series of clinical acidoses, the serums varied from 7.55 to 7.2 and the oxalated blood from 7.3 to 7.1. In experimental acidosis in dogs, a pH of 6.9 has been encountered in both serum and blood just before death.

23. **Urobilin in Stool in Pernicious Anemia.**—In six cases of pernicious anemia with splenectomy, examined by Robertson, the urobilin output which had previously been high, showed a marked decrease immediately after operation. In two cases in which the urobilin later returned to a high

figure, as well as one case in which there was a persistently increased output, showed definitely less improvement than the two cases in which the urobilin remained normal. Three of the four patients transfused gave evidence of a resulting bone marrow stimulation and at the same time showed a temporary increase in urobilin excretion. The one case in which transfusion was without effect showed no such increase. In three patients treated with salvarsan, there was practically no effect, either on the course of the disease or on the urobilin excretion. It seems fair to Robertson to conclude that: 1. Variations in the urobilin output may be taken as an index of corresponding changes in the course of the disease. 2. Such variations in the urobilin may occur before there is any change in the number of red cells. 3. The determination of the urobilin output as an index of blood destruction is the most accurate means we have of estimating the effect of treatment.

24. **Splenectomy in Congenital Hemolytic Icterus.**—In a child with congenital hemolytic icterus splenectomy was followed by a disappearance of the discoloration of the skin, a rapid improvement in the condition of the blood and a striking improvement in general health. Metabolism studies before and after splenectomy gave the following results: A slight positive nitrogen balance before splenectomy was followed by an increased retention eight days after operation. The output of uric acid showed a decrease of 47 per cent. after operation. In the period directly after operation a change in the partition of creatinin and creatin elimination occurred; the total creatinin, however, showing but slight change. Other urinary nitrogen constituents showed no variations from the normal, and no change was found in the hydrogen ion concentration. The utilization of nitrogen was good at all times. Fat metabolism was normal. There was a large loss of iron through the feces before splenectomy followed by a decided decrease (40 per cent.) after operation. The excretion of urobilinogen and urobilin in the feces was markedly diminished after splenectomy; the amount after operation was about one-ninth of that excreted before splenectomy.

25. **Hemorrhage and Occlusion of Carotid Arteries.**—The authors found that hemorrhage caused a marked augmentation of the reaction to nicotin but slight or no augmentation of the reaction to epinephrin. Occluding the carotids in most instances leads to similar results. The authors suggest that the augmented reactions are probably due to increased irritability of the vasoconstrictor center and that the phenomenon is probably an adaptive arrangement tending to preserve normal circulatory conditions.

26. **Diphtheroids.**—Examination of the charted characters, the morphology notes and the pictures in thirteen cases, leads Fox to state that no one bacterial variety with definite morphologic and cultural characters has been isolated from eleven cases diagnosed as Hodgkin's disease (Rosenow 5, Kolmer 2, Fox 4) to which may be added a case of endothelioma of the lymph nodes. Diphtheroid bacilli have been isolated from glands in at least two cases having no clinical or anatomic resemblance to Hodgkin's disease and from a case of mediastinal tumor. The author points out that diphtheroid rods may be isolated in cases of Hodgkin's disease and other adenopathies, but there is no uniformity in biology, and morphology among the strains isolated by three observers in clinical and pathologic Hodgkin's disease. Diphtheroid rods, similar in biology and morphology to those found in Hodgkin's disease, may be found in enlarged glands in cases of chronic atrophic arthritis and other conditions. Diphtheroids have been found in glands the seat of a neoplasm, and in the enlarged glands near a neoplasm. There is great similarity in all respects between the gland diphtheroids and those found in normal and pathologic seats in the body, the so-called pseudodiphtheria bacilli. In one case, in which autogenous vaccination was given a fair trial, the patient has died. Another patient, already improving under the Roentgen ray, continued to improve with autogenous vaccination and no Roentgen ray. In arthritis cases the patients receiving vaccine consisting wholly or in part of diphtheroids, showed some improvement. Much granules have not been found in sections of lymph granulomas of the Hodgkin's type.

27. **Use of Atophan for Eliminating Uric Acid.**—In six cases examined by Fine and Chace there was a general relationship between the degree of response to the administration of atophan on the one hand, and the extent of non-protein nitrogenous retention and the clinical pictures on the other. Their observations lend some support to the view that abnormal renal cells would be expected to prove less responsive to the action of atophan than are healthy cells.

29. **Treatment of Cystinuria.**—According to Smillie cystinuria is best treated by a low protein diet, with the addition of sufficient alkali to keep the urine alkaline. Cystin crystals will practically disappear from the urine of a cystinuric when sufficient sodium bicarbonate is added to the diet to render the urine alkaline. The amount of sodium bicarbonate necessary to render the urine alkaline, when the patient is on a nitrogen intake of 10 gm., or more, is greater than can be well borne by the stomach. Sodium bicarbonate does not influence body metabolism in cystinuria but simply renders the cystin soluble.

34 *Some Experiences with Friedenthal Milk. E. A. Riesenfeld, New York.

30. **Relationship of Syphilis to Chorea of Sydenham.**—Koplik took eleven successive cases of chorea in which the age range was from 6 to 13 years. In five of these cases there was an endocarditis on admission to the hospital, with an evident lesion of the valves, in three cases a distinct history of rheumatism or rheumatic pains, in ten cases a Wassermann reaction was made, and in eight the result was satisfactorily negative. In two, the reaction for one reason or another, failed but was not positive. In all the cases there was absolutely no stigmata of syphilis, hereditary or otherwise, nor could syphilis be traced in any way in the family history. Nine patients were injected with neosalvarsan in doses ranging from 0.15 gm. to 0.4 gm. of the drug. Of seven patients thus injected, once or repeatedly, the effect, in that the symptoms immediately subside, was not observed. Even after second and third injections the chorea continued to run its accustomed course. The average duration of the disease, after the last injection of the drug, was thirty-six days in seven cases. In another case a nephritis resulted and the patient was ill with chorea for some weeks after, though finally a recovery took place. Koplik concludes that there is nothing in these results to warrant any assumption of a possible syphilitic or parasyphilitic influence as a causative factor in chorea of Sydenham. He does not regard salvarsan as an agent of any value above what has hitherto been in vogue in the treatment of chorea minor, nor does he feel warranted in tracing any relationship between chorea of Sydenham and hereditary or acquired syphilis.

32. **Meningitis in Newborn.**—The case cited by Herrman, he says, is the only case of pneumococcus meningitis in the newborn reported. The case was especially interesting on account of the absence of fever and later a marked subnormal temperature, and on account of the entire absence of meningeal symptoms, so that the necessity for a lumbar puncture was not even thought of.

34. **Experiences with Friedenthal Milk.**—Of twenty-one infants placed on Friedenthal's milk by Riesenfeld, nineteen made a steady and normal gain in weight, with an average of 4 ounces per week, infants under 3 months of age making the greater progress. Two infants who failed to gain showed a marked intolerance for the high fat and sugar content of Friedenthal's milk and could only be given food containing low quantities of sugar and fat.

42 *New Method of Treating Flat-Foot. P. B. Howard, Newtonville.

36. **Common Shoulder Injuries.**—Emphasis is laid by Risley on the following points: Diagnosis in shoulder injuries is not made by clear cut signs and symptoms, but only in a careful process of exclusion and roentgenoscopy in every case. The Roentgen ray is of the utmost importance in every case as it often reveals the underlying cause of a persistent bursitis to be some of the frequent lesions of the greater tuberosity or acromion, which are often overlooked unless especial search is made for them. About 60 per cent. of subacromial bursitis cases are of the occupational type. The remaining 40 per cent. have as an underlying cause in the great majority of cases, some lesion of the greater tuberosity or acromion. The diagnosis of ruptured supraspinatus tendon should not be made until at least three months of nonimprovement have elapsed.

Cases of long standing bursitis with adhesions give a picture identical with that of ruptured supraspinatus tendon and give extremely satisfactory results from operation. Calcareous deposits in the subacromial bursa may be spontaneously absorbed. The term "insertion fracture" should be substituted for the nondescriptive term of "sprain fracture." Occupational neurosis per se does not exist in the shoulder joint. Injuries to the brachial plexus are rare. The percentage of patients benefited will be greatly increased by early exploratory operation. Slight injuries to the greater tuberosity and acromion process and arthritis of the acromioclavicular joint are of far greater importance than is generally supposed in prolonging disability after shoulder injuries. Risley lays especial emphasis on the importance of these seemingly trivial injuries to the shoulder joint as factors to be considered in diagnosis, prognosis and treatment.

38. **Schick Test in Children.**—Of 126 children, ranging in age from 5 to 16 years, Linenthal and Rubin found thirty-six susceptible to diphtheria and ninety immune. Antitoxin of 750 units administered to the nonimmune produced an immunity which did not last over four weeks in 50 per cent. in several as long as eight weeks, and in six children the immunity conferred by the antitoxin persisted after five months. With the exception of the six children with the persistent antitoxin immunity and one child who gave negative reaction the first time and a positive the second time, the results of two tests, five months apart, were uniform. The authors regard the test as of great value in determining susceptibility to the disease and thus serves as a guide to determine in the event of exposure to diphtheria, who should and who should not receive prophylactic doses of antitoxin. Persons naturally immune will thus be saved the annoyance and the possible disagreeable results apt to follow the injection of horse serum.

40. **Auricular Fibrillation and Complete Heart Block.**—White cites the case of a patient showing heart block and auricular fibrillation whose heart rate rose from 27 with complete block, to 47 with partial block during the administration of digitalis and coincident with marked clinical improvement. The ventricular complexes of the electrocardiogram changed in character simultaneously with the decrease in the degree of block, the change in the R suggesting a more normal conduction in the ventricle. The spontaneous return to a complete block was accompanied by a continuation of the patient's good health. The block was not vagal in origin, atropin having no influence on it.

42. **Method of Treating Flat-Foot.**—After having trouble with his own right foot, Howard decided to try an experiment which would give support to the arch in all positions and free play to the muscles, at the same time being perfectly flexible and self-adjusting. Taking a cast of his foot he made a model and had a rubber factory make up several arch supports or shaped rubber bulbs filled with air. These he covered with leather and tried them out in his shoe with much satisfaction. In general the arch above conforms to the arch of the foot below, it fits the shoe, and on the inner side it is reinforced to prevent bulging. This is encased in leather, which is extended under the heel for an anchor, so to speak, and forward it tapers off just a little in front of the arch support. The support is made and encased in such a way that the air is held absolutely under the arch of the foot, and as the contour of the arch of the foot changes, the arch support changes also, still exerting on the arch of the foot the same upward pressure. It allows free muscular action all of the time as the foot is flexed or extended in locomotion.

34. **Experiences with Friedenthal Milk.**—Of twenty-one infants placed on Friedenthal's milk by Riesenfeld, nineteen made a steady and normal gain in weight, with an average of 4 ounces per week, infants under 3 months of age making the greater progress. Two infants who failed to gain showed a marked intolerance for the high fat and sugar content of Friedenthal's milk and could only be given food containing low quantities of sugar and fat.

with old tuberculin and the Wassermann antigen, the authors hold that the probabilities are that the patient is a leper. However, negative results with old tuberculin are not sufficient to exclude a diagnosis of leprosy. On this occasion they observed no case of leprosy that reacted positively only with old tuberculin.

85. **Ocular Lesions from Injection of Streptococci.**—As the outcome of a long series of experiments in which animals were injected intravenously under uniform conditions with streptococci from rheumatism, from appendicitis, from ulcer of the stomach, from cholecystitis, from erythema nodosum, from herpes zoster, from parotitis, from pyorrhea, from tonsils, and from dairy products, Rosenow has had opportunity to study the eye lesions in forty-eight animals. The lesions may be classified as follows: (1) unilateral panophthalmia in five instances (twice following injections of strains from rheumatism and herpes zoster as isolated, and once in each case after one animal passage, and once in a rabbit injected with a streptococcus mucosus from the eyeball in a case of metastatic panophthalmia following tonsillitis and otitis media); (2) hemorrhages in the limbus, with or without episcleritis, in fourteen instances (four times following injection of laboratory strains after they had attained a certain grade of virulence, three times with rheumatic strains, twice with strains from appendicitis, twice with strains from herpes zoster and once each with strains from erythema nodosum, myositis and from butter); (3) iritis or iridocyclitis nine times (four times after injection of certain laboratory strains, three times with rheumatic strains, and twice following injection of streptococci from small pus pockets in tonsils of otherwise normal individuals); (4) conjunctivitis, usually bilateral, occurring frequently, in ten instances associated with the streptococci injected (once each with streptococci from appendicitis, herpes zoster and rheumatism, once with streptococci from butter, once with streptococci from the pus pocket in the tonsil of a cow, twice after injection of a laboratory strain, and three times after injection of strains from pus pockets in tonsils from approximately 100 individuals); (5) ulcer of the cornea due to the organism injected, observed only once, after injection of a strain of streptococcus from the muscle in calcifying myositis in a man. Lesions similar to these occurred with or without herpes in twelve animals injected with the strains from herpes zoster. Herpes of the conjunctiva followed injections or streptococcus from the tonsil in ulcer of the stomach in a cow. Hemorrhages in the retina were not often looked for, but were found in two instances.

86. **Production of Antibodies after Removal of Organs.**—In the dog complete removal of the stomach, of the small intestine, or of the thyroid according to the observations made by Hektoen and Curtis does not interfere with the development of the agglutinin and opsonin for rat corpuscles after intravenous injection of rat blood. Pancreatectomy, complicated by intussusception and by rabies, resulted in a diminution in the amount of antibodies that accumulated in the blood. Simultaneous removal of spleen and of pancreas appears to have about the same depressing effect on antibody production in dogs as removal of the spleen only. Removal of the small intestine and ligation of the mesenteric artery before the injection of rat blood in dogs may be followed by a longer latent period after the injection of antigen than in normal dogs. Adrenalectomy at the height of the antibody curve in dogs does not change the antibody content of the blood serum. In rats, removal of about one-half of the liver appears to have no effect on the development of lysin for sheep corpuscles. The results recorded indicate that the mechanisms for the fabrication of antibodies are quite secure from certain disturbances, and they are in no way contradictory of the current view that these mechanisms are located in the blood-forming organs.

87. **Roentgen Ray and Antibodies.**—Repeated exposures of white rats to the Roentgen ray immediately after the injection of sheep blood did not interfere in any noteworthy degree with the production of lysin when the exposures, though sufficient to reduce the number of leukocytes in the blood, have no definitely detrimental effect on the general health of the animals. When the exposures are commenced some days before the injection of sheep blood and continued in such manner that the number of leukocytes is greatly reduced for from fifteen to twenty days after the injection of sheep blood, Hektoen found that the formation of lysin is restrained to a marked degree. This may be accomplished without any appreciable effect on the general health. In such animals the spleen, lymphatic tissues, and thymus are greatly reduced in volume and the bone-marrow changed. In the blood, the granular leukocytes are increased relatively and the total number of leukocytes is much below normal. A single prolonged and eventually fatal exposure to the Roentgen ray immediately before the injection of sheep blood may prevent any formation of lysin for the next eight days or so, or lysin may be produced after a longer period of latency than in the control animals. The results harmonize with the view that antibodies are produced in the spleen, lymphatic tissues and marrow, as these structures suffer most directly from the action of the Roentgen ray. The results indicate also that one reason why the lymphocyte appears to be an important agent of defense in tuberculosis and other conditions may be its power to form antibodies. In view of the destructive action of radium on the leukocytes and blood-making organs, it is altogether likely that it will be found to have the same general effect on the production of antibodies as the Roentgen ray.

89. **Fate of Foreign Erythrocytes in Rabbit.**—It is the purpose of Cary's paper to contribute evidence that foreign blood cells introduced into the circulating blood stream are engaged by and destroyed within certain fixed tissue cells of the liver and spleen.

1. **Peritoneal Exudates.**—An estimation of the character, significance and prognostic value of peritoneal exudates was made by Carslaw. His results are based on an examination of eighteen cases of appendicitis, four cases of perforated gastric or duodenal ulcer, one of tubo-ovarian abscess, and of femoral hernia, operated on by him. He found that the mononuclear phagocytes in the peritoneal exudate consist of two different types of cells, endothelial cells and large mononuclear leukocytes, which not only have two distinct sources of origin, but also can easily be distinguished from each other in all stages of their functional activity by the indophenol-synthesis test for oxydase. Examination of the peritoneal exudate is of great prognostic value in cases of spreading peritonitis, as it indicates the amount and virulence of the bacterial invasion and the extent to which the reactive forces of the peritoneal cavity have been, or are being developed. In considering the significance of the relative number of the various cells, their phagocytic activity, and their healthy or degenerated character, the duration of the bacterial invasion must always be borne in mind. The contention that an immediate examination of the exudate in cases of spreading peritonitis supplies information which indicates whether drainage of the peritoneal cavity is necessary or whether primary closure may be employed, Carslaw says, must be modified by three facts, namely: (a) Local drainage is often necessary although drainage of the general peritoneal cavity may be not only unnecessary but also injudicious. (b) Drainage of the general peritoneal cavity is only called for in very exceptional cases. (c) Effective drainage of the general peritoneal cavity is impossible.

5. **Study of Actinomycosis.**—Cope urges that actinomycosis should always be considered in the diagnosis in the case of any newly formed subacute or chronic swelling in the region of the mouth, face, neck, thorax, or right side of the abdomen. Pus from every abscess should be examined as a routine practice. In any subacute or chronic lesion, the discharge needs to be examined repeatedly. Peribuccal infections comprise the majority of the cases. Here the organism enters most often through the mucous membrane of the alveolar margin near a carious or erupting tooth, or through the tooth socket into the jaw. The fungus is taken in with the food, and lodges round the teeth. The features of the hard peribuccal form are characteristic and can often be diagnosed long before pathologic investigation can give much help. Treatment by the administration of iodids, by vaccine therapy, and by surgical measures, promises the best results.

11. **Treatment of Gunshot Wounds.**—The advantages claimed for this method of treatment by Gray are: Healing by first intention is assured in the vast majority of properly selected cases. Much time is thereby saved. Some wounds, which would otherwise require months to heal, are soundly united in the course of from ten to fourteen days. The soldier is thus available for duty again at a much earlier date. The amount of attention required to be given by the medical officers and nursing sisters, etc., is greatly reduced. Much pain is avoided. The amount of dressings required is reduced to a minimum, and in this way expense is lessened. Complications which may arise from the presence of a septic wound are avoided. A more sightly scar is obtained. Because of the absence of the contraction which would accompany the formation of a large cicatrix, there is less impairment of function in the part concerned. In the case of head injuries, excision of the wound, especially in some, apparently trivial, injuries, provides a means of ascertaining, with greater certainty than by any other method, whether depressed fracture or injury to the brain coexists. Gray says that healing by first intention may be procured in practically all cases in which the surfaces of the new wound can be brought into accurate approximation without much tension. In rare cases, when the wound is deep, approximation in the depth has to be dispensed with and drains are introduced for a short period—until one is assured that aseptic healing will occur. In some cases it is necessary to adjust and fix the parts of the body adjacent to the sutured wound so that the fullest relaxation is secured. The mere length of a wound is no bar to operation. It is not necessary to wait until the wound is surgically clean, in fact, in most cases, the sooner the excision is made the better. Only when a large "bank" of inflamed tissue surrounds the wound is immediate excision inadvisable on account of the septic condition of the wound. By vigorous "salting" (hypertonic treatment) such wounds are usually rendered suitable for excision in from twenty-four to forty-eight hours. Other

of the maneuver. The condition of Babcock's patient necessitated implanting one of the ureters into the rectum, so that only one was implanted into the appendix. He was a poor operative risk at best, and died two days after the intervention. Babcock does not believe that the uretero-appendiceal anastomosis possesses any great advantages, as it does not avoid contraction of the scar of the divided end of the ureter, the resulting stenosis being one of the main causes of renal infection after this type of operation.

A successful implantation of the ureter into the loin is recorded by Martin,[29] in a case of carcinoma which necessitated removal of the bladder and the uterus. With the exception of a tendency of the epithelium to cover the orifice of the ureter, which made dilatation necessary from time to time, the condition was all that could be desired. Symptoms of suppurative inflammation of the kidney sixteen months after the operation led to a nephrotomy, from which the patient made a good recovery and is reported well and comfortable seven months afterwards.

Implantation into the rectum with good results is reported by Arumugum,[30] of Bungalore, India, in two cases of extroversion of the bladder. Both patients were seen again four and a half years after the operation and both (the younger a boy of 13) were able to control urine five or six hours during the day and eight hours or more during the night.

The care of the ureters, we thus see, presents many difficulties and the "ideal method" has not yet been devised. Investigators are busily engaged in experimental studies that may possibly lead to the Eldorado of this branch of surgery. I regret that I can do no more than mention in this connection the excellent and brilliant work, among others, of our own Eisendrath,[31] Coffey,[32] Jones[33] and Barber;[34] that of Schmidt and Kawasoye,[35] in Germany; Chiasserini,[36] in Italy; Zaaijer,[37] in Holland; and the Russians, Shisko,[38] and Iljin.[24]

An unusual case of double ureters with intravesical ballooning of the lower ends is described by Young.[39] Both ureters opened into the bladder through a diverticular orifice. This diverticulum could be turned inside out at will, and whether so turned or not it was seen to be made up of a greatly dilated ureter. A plastic hernia operation was performed with apparently favorable results, as there was no evidence of intravesical ballooning when the patient strained. In a cursory review of the literature Young failed to find another like instance.

In a case presenting three ureters, one opening extravesically, Furniss[40] operated by making an incision into the mucosa, covering the under surface of the urethra over the catheter. Unfortunately the incision went into the much-dilated ureter. A sound was then passed into the bladder, and its mucosa and the mucosa of the sac were united with fine catgut in such a way that the distal end was obstructed. Thus the ureter was made to enter the sac, and from there to the bladder a fistula was formed. At a second operation, thirteen days after the first one, the ureter was dissected backward for 1½ inches. It had increased in size toward the renal end. A suture was placed through the end of the ureter and a sound passed into the bladder. This made the bladder bulge backward and to the left; a small incision was then made into this. The suture was held to the sound and the ureter pulled into the bladder, where it was held with one suture through the bladder and a part of the ureter. The suture pulling the ureter into the bladder was attached just below the clitoris. Postoperative cystitis yielded to treatment and recovery was perfect.

An aberrant, supernumerary ureter was treated by Hartmann[41] by resecting the dilated portion, freeing it for about 1.5 cm., and implanting it into the bladder per vaginam. The results were good. Subsequent cystoscopy showed that the implanted organ had become somewhat flattened. The two normal ureters were entirely independent of the implantation point.

Duplication of the ureters is not an unusual phenomenon, but the abnormality is frequently not suspected until some postoperative condition calls attention to the possibility of its existence. After an operation for cancer of the cervix, during the course of which Worrall[42] had traced the ureters to the bladder and isolated their pelvic portion, the meager amount of urine passed by the patient and her general poor condition led to the suspicion of the presence of double ureters, and that the main canal on each side had been tied. A second operation was done. The ureters were easily located, as they were both dilated above the ligatures. They were disinterred and after splitting their ends, were implanted into the bladder close to the other ureter on each side, which could be plainly seen. Leakage persisted for several months, but complete recovery was finally established seven months after the operation.

While operating in a case of carcinoma of the rectum, Samborski[43] found reduplicated ureters separated from the surrounding tissue and connected with each other by the intervening cellular tissue. He transplanted the two organs as one; the cellular tissue connecting them served conveniently for attaching them to the intestines. The fold of the rectum covered both ureters as if they were one body, and the orifices of the two ureters were sutured in as one, with a single opening of the rectum. The right (single) ureter was somewhat dilated; this was also sutured into the rectum. Metastatic lesions were found in the right ureter. The patient did well up to the twelfth day, when he gradually began to fail, though there was no rise in temperature. Death ensued on the seventeenth day.

Intravesical cysts, while not very rare, have not frequently been diagnosed by means of the cystoscope as Gayet[44] was able to do. He removed the growth by a hypogastric incision, a method not usually employed for the purpose. After the incision was made, the cyst could be seen in the right ureter and the fluctuation of the tumor showed that urine had found its way into the cyst, although no orifice could be detected. An incision was made at the base of the tumor and a pouch, from which a certain amount of urine escaped on pressure, was removed. A crown suture of fine catgut was placed at different points through the ureteral and the vesical mucosa. The bladder was sutured and space allowed for drainage tube. A permanent catheter was introduced. On examination of the pouch, the orifice could be located only by means of a magnifying glass. The lesion was evidently a congenital one.

Pietkiewicz[45] attributes cystic dilatation of the vesical ends of the ureters primarily to a stenosis of the ureteral orifice, and resulting in urinary stasis in the lower portion of the ureters. He describes two such cases with prolapse of the ureter through the urethra. This is perhaps one of the most unusual diseases of the urinary system. Ten cases have been reported as occurring in little girls, but Pietkiewicz knows of only two other cases besides his own, one reported by Simon and the other by Hartmann, in Jena. Diagnosis was made at operation in all these cases. Pietkiewicz was the first to use the high incision for the operation (1909).

The tumor in his first case was seen on examination at the dilated meatus of the urethra, and preliminary treatment consisted of removal under light narcosis. At cystoscopic examination the tumor was seen, the base of which covered the greater part of the trigonum. The right ureteral orifice was not visible. The left one appeared in the form of a club-shaped pulsating protrusion, the point of which was concave with a tiny, scarcely visible, ureteral opening. At operation the cavity of the cystic dilatation was found to communicate directly with the dilated lumen of the ureter. The walls of the growth were dissected off and the wound closed with sutures. A wide gaping orifice was now visible, from which urine flowed periodically. Cystoscopy a week later showed normal bladder mucosa and the urine flowing in a rhythmic stream from a normal ureteral orifice. The correction of the stenosis on the other side was postponed for another occasion. In the second case described by Pietkiewicz, the bladder tumors were unusually large and the condition was complicated with pyelonephritis. The tumors were removed at several sittings, without anesthesia, by means of a knife encased in a blunt-end metal sheath introduced through the urethra. All symptoms disappeared as soon as the stenosis at the ureteral orifices was removed.

Pietkiewicz sketches the pathologic process thus: The club-shaped protrusion (Case 1) of the left ureteral cushion represents the initial stage of the dilatation, the pear-shaped tumors of Case 2 being the second stage. The condition around the ureter in Case 1 showed that the right kidney was secreting urine, but no regular rise and fall of the tumor could be noted after the prolapse had been corrected. This stationary form, which differs little from a genuine cyst, would represent the last stage of the dilating process. As long as the dilated ureteral end remains in the first or in the second stage, that is, as long as the walls of the tumor retain their muscular function and take an active part in the ureteral peristalsis, there is little or no danger of a prolapse. It is the third stage, when the tumor has attained a certain size and its walls have lost their muscular power, that represents a favorable condition for prolapse. The dilated end of the ureter may easily be carried by the force of the urinary flow into and occasionally tampon the inner urethral orifice. The urinary troubles that result force the patient to help by means of pressure and bring about the prolapse.

Algave and Papin[46] describe a case in which the ureter abnormally opened into the urethra and had caused enormous dilatation of the pelvic and lumbar regions. They succeeded in passing the catheter into the abnormal orifice, which seemed dilated into a wide pouch, from which pus was evacuated. The collargol picture showed that this abnormal ureter was markedly dilated for its entire length. The kidney was fused with the suprarenal capsule and was removed with difficulty. These authors seem to think that this condition is a more frequent occurrence than is generally supposed, and that it is seen more often among woman than among men.

Juvara[47] mentions a case of aberrant ureter opening into the vulva to the right of the ureteral orifice. The abnormal canal was found to join the ureter at a sharp angle directly below the kidney pelvis. It was resected for a distance of 18 cm. Under the microscope it presented typical ureteral structure.

Hernia of the ureters is not frequent. Gilberti[48] has collected reports of thirty-three cases. He advises burial of the ureter into the bladder as the most successful procedure when conditions permit.

REPORTS OF CASES

Case 1.—Mrs. W., aged 27 years, was admitted to the Jefferson Hospital complaining of pain in the right lumbar region. There is a family history, on the maternal side, of cardiorenal disease for several generations back. The patient herself, with the exception of an attack of pneumonia at 24 years, had always enjoyed good health. She is the mother of two healthy children, 12 and 9 years of age. Menstrual periods have always been more or less painful.

Her present trouble dates back two years, with the sudden onset of pain in the right lumbar region, radiating along the course of the ureter into the right labia. Intermittent attacks (usually coming on before the menstrual period) have recurred since then with more or less violence. Of late during the greatest distress the pain radiates to the left labia and the left thigh; there is some dyspnea, and urine seems to be decreased followed by an increased flow. The attacks last several hours and are always followed by nausea, vomiting, soreness and exhaustion.

The left kidney could not be palpated at examination. A smooth mass, moving with respiration, was palpated in the right hypochondrium; tenderness was marked over the right kidney.

Cystoscopic examination showed a normal bladder; the ureteral orifices were also apparently normal. The pyelogram disclosed a displaced right kidney, small stone in the kidney pelvis, kinked ureter and hydronephrosis. In the left kidney region there was no collargol shadow seen, which suggested a unilateral right kidney.

At operation the kidney was approached through the Koenig incision. The upper part of the ureter was distended and kinked, the elbows of the kink being firmly adherent. The renal pelvis was also much distended. When the adhesions surrounding the kidney and ureter were loosened up, the second ureter was found and traced to the extreme upper portion of the dilated kidney pelvis. The pelvis was then incised, and, after the calculus was removed, a part of the renal pelvis was resected and repaired by double-line suture. A nephropexy was then done—four sutures, two on either side through the renal capsule, incorporating a small amount of cortex—and the organ sewed in position. Considerable fat and fascia were transplanted along the ureter at the site of kinking in order to prevent another angulation. After the kidney was fixed, the position of the ureter at its outlet from the pelvis was found at the lowest point of the repaired renal pelvis. The second ureter was traced down to the lumbar vertebra, where it crossed over to the left side, entering the bladder approximately in a normal position. This ureter was ligated and resected. The patient made an uneventful recovery, being discharged five weeks after operation. When seen again eleven months later, she was in the best of health, and had had no recurrence of the renal pain.

Case 2.—H. M. P., aged 32 years, came under observation Sept. 13, 1913, with a history of repeated attacks of left renal colic, during the past eighteen months, increasing in severity as time went on. Five roentgenograms taken during this period, as well as a sixth one after his admission to the hospital, all gave a negative picture. The catheter introduced into the left ureter met an obstruction at about 10 cm. from the orifice. The stricture, thus found, was treated by gradual vesicle dilatation for one month on alternate days, resulting in relief. The patient was dismissed apparently well. Another severe attack during the next month obliged him to return for further treatment. It was now decided to explore the ureter. The incision was made along Poupart's ligament and the great vessels exposed at the ileosacral junction. The ureter was easily recognized, a catheter having been previously inserted. The ureter was dissected from its peritoneal attachment to the point of narrowing, above which it was somewhat distended; a small stone was detected on palpation and removed through a longitudinal incision approximal to the stricture; the incision was continued for about 1.5 cm., dividing the stricture freely. A transverse line of two-tier sutures was inserted, increasing the constricted lumen beyond that of normal caliber. The wound was closed with a cigarette drain to provide against leakage. No leakage occurred; the patient made an uneventful recovery and is well, one and a half years after operation.

I desire also to report a case of successful implantaken of the ureter into the loin.

Case 3.—W. B., hotel clerk, aged 33, came under observation, November, 1904, with a history of sudden attack of severe renal colic, referable to the right kidney. The patient had had four severe attacks prior to his admission into the hospital. By palpation over the right loin a large painful mass was detected. The urinary analysis showed a large quantity of pus and red blood cells. The Roentgen ray revealed a shadow of a good-sized stone in the pelvis of the kidney. The patient was profoundly toxic. At operation pyonephrosis was found, with stone in the pelvis. It was decided, owing to the grave condition of the patient, to drain the kidney, preliminary to doing a nephrectomy. It was also found convenient at this time to bring the ureter into the loin, where it was fixed in position with a few interrupted sutures, with a view of expediting the secondary operation. The patient improved rapidly and refused further operation. He was discharged from the hospital the thirty-third day following his admission. Nearly twelve years have elapsed since the ureteral implantation. The patient has enjoyed the best of health and says that he does not experience much inconvenience from the urinary drain in the loin.

1819 Walnut Street.

Rufus of Ephesus.—To generations of practitioners unworthy to hand him ligatures Rufus of Ephesus (Reign of Trajan, early part of second century A.D.) was known by the "pilulae Ruffi," "the pills I would not be without"—"pilulae sine quibus esse nolo"—still in the British Pharmacopoeia as the pill of aloes and myrrh. In the brilliant Ionian profession of the early days of this era Rufus doubtless had predecessors and teachers, but he stands out a strong, clear figure, a great "magister chirurgiae," a title justly earned by his remarkable contribution to the surgery of haemostasis.—Osler.

URETERO-ENTERIC ANASTOMOSIS

A FURTHER EXPERIMENTAL STUDY *

W. HOWARD BARBER, M.D.
NEW YORK

The problem of the disposition of the ureter that has been separated from the bladder by accident or reason has engaged the attention of many thoughtful and ingenious surgeons for the past sixty-five years. The feat has been attempted from different points of view. To prevent peritonitis, Lloyd and Simon[1] worked extraperitoneally. To preserve the immediate ureteral vesical relations, Pisani, Peterson,[2] Maydl and Moynihan transplanted both of the ureters and the adjacent portions of the bladder involving the area of the trigonum vesicae. To accomplish both at once, Bergenhem[3] removed the ureterovesical rosettes separately and extraperitoneally.

Again, to protect the transposed ends of the ureters from contamination by the fecal stream, Gersun,[4] Tizzoni, and Pozzi substituted for the bladder evaginated intestine and transplanted the severed ureters into it. Martin,[5] Kryinski,[6] Fowler,[7] Boari[8] and numerous others, without removing any portion of the bladder or without creating one artificially, anastomosed the ureters to the lower bowel directly. They endeavored to elaborate a defensive barrier in the union of the extreme caudal ends of the ureters with the normal bowel. Tuffier, Coffey[9] and Beck[10] attempted the same result, but allowed the ureteral ends to protrude into the intestinal lumen. All these workers[11] have striven to produce, largely through anatomic study, a perfectly functionating entero-ureteral anastomosis.

Reviewing these different technics in entirety, they appear to have been suture methods (with the possible exception of Boari's, in which a button was used) and contrivances retaining the ureterovesical valve or its equivalent. Especially painstaking seem to have been the efforts spent to create resistance at the caudal end of the ureter equivalent to that presumably present in the normally intact ureter. Fowler[7] pertinently criticized the Maydl operation for "making no allowance for the changed pressure conditions of the rectum" and for involving "extensive dissection," and Kryinski's method in that the "pressure exerted was fallacious in accomplishing the result" desired, while at the same time Fowler buried his ureter for an arbitrary distance and consequently with an unknown resistance in the muscular fibers of the rectum. Coffey[9] called his enteric implantation of the ureter "physiologic," while simulating the anatomy of the ureterovesical termination. The latter method has been followed by C. Mayo[12] in four cases recently reported by him. It seems to me, however, that the physiology of the ureter has for the greater part been disregarded, for it is believed at the present day that the ureterovesical valve is negligible physiologically. This dissimilarity between the pressure conditions of the intestinal tube and the closed urinary bladder further emphasizes the impertinence of a vesical ureteral termination in the bowel.

> The operator who cuts off both ureters from the bladder and transplants them into the colon, must experience a certain and unavoidable anxiety—an anxiety that only further experience will overcome, that is born of the feeling that he has burned his ship behind him and has staked all his patient's chances, all his hopes, in the hazard of the game. It is the utter hopelessness of remedying the evil that must make any conscientious operator vacillate many times over before deciding to embark on so perilous an undertaking.

A number of salient physiologic facts were brought out by our laboratory studies during the past two years. It was determined by Draper and Braasch[13] at the Mayo Clinic in 1911 that the ureterovesical valves may be destroyed in the presence of purulent cystitis without probable kidney infection. It was evidently probable from the studies[14] presented at Atlantic City in June, 1914, that of the two factors, namely, the ureteral peristalsis and the mechanism of the ureterovesical valve, the peristaltic factor is often the vitally important one in the determination of a possible renal infection. Furthermore, it was shown that when this ureteral function was seriously impaired, amounting virtually to a ureteral paralysis, and the ureterovesical valve function was left intact, hydronephrosis followed in 75 per cent. of cases.[15] The latter experiments have been repeated during the past fall with the following results:

> In Dogs 16 and 17, the *infected vesical body had become* a ureteral calculus. The expected results followed in a more accentuated form, but because of this new variant, these experiments have been omitted from consideration.
>
> Dogs 6 and 22 are negative.
>
> Of the remaining, 50 per cent. are hydronephrotic and 83⅓ per cent. are hydronephrotic or have dilated ureters. These results may be seen to compare favorably with those already referred to.

Hence, it appeared that an operation to have substantial functional value must, above all, involve the least possible traumatization of the ureter. Furthermore, it must be granted that some degree of traumatization is inevitable and that its peristaltic efficiency is proportionately impaired. Therefore the caudad resistance must be proportionately decreased if the ureter is expected to empty itself. For this reason, not only the resistance of a normal valve appeared too great, but also all resistance arising from artificially created plastics appeared too great. The problem then remains: How anastomose the ureters with the lower bowel with the least interference with their peristaltic function and with the establishment of caudad resistance physiologic for them in their necessarily impaired states?[16]

TABLE 1.—REPORT ON SECOND SERIES OF URETERAL TRAUMATIZATION, DEC. 7, 1914

Dog No.	Days of Life	Pathologic Condition of Urinary Tract
23	50	Dilatation of cephalad ureter cystitits
6	23	Purulent cystitis
16	12	(Abdominal organs negative.) Left hydronephrosis; hydro-ureter; pyelonephritis. Right pyelonephritis. Sup. cystitis; acute vesical retention; urethral calculus.
14	15	Left hydronephrosis; cystitis
17	15	Cong. kidneys. Left hydro-ureter; cystitis; urethral calculus
13	15	Cong. kidneys; cystitis. Dil. of cephalad ureter
15	14	Left hydronephrosis; cystitis
24	9	Left hydro-ureter; hydronephrosis; cystitis
80	21*	Left hydronephrosis; cystitis
82	11	Left pyonephrosis; hydro-ureter; cystitis
5	50*	Left dil. of cephalad ureter; cystitis
22	10*	Negative
83	20*	Left hydro-ureter
81	16	Left hydronephrosis; hydro-ureter; cystitis

* Etherized.

The following operation represents an attempt to correlate the experience of others with the recently obtained physiologic knowledge of the ureter:

A mesoventrad incision is made in the lower abdomen. The bladder is drawn toward the wound. One or both ureters may be created as follows: identify, doubly ligate, and cut between ligatures; attach a large, straight cutting needle to the cephalad end by its ligature, and penetrate the sigmoidal wall in the plane of the mesenteric reflection. Drive the needle with the aftercoming ureter obliquely for from 1.5 to 2 cm. through the wall, with the colon held on the stretch. At a point approximately 1 cm. obliquely distant from the point at which the needle enters the lumen of the sigmoid, penetrate the colon perpendicularly, drawing the ureter out on the skin. Suture the ureter to the skin by its ligature and close the wound about that part of the sigmoid traversed by the ureter. It is of advantage to strip the ureter in its caudad one fourth and to free the distal two fourths digitally to avoid angulations, torsion or harmful tension. It is important to see the ureteral ends distended before the closure of the abdominal wound in order to make certain that the urine flow is not obstructed. It is convenient to divide the ends incompletely to free the urine after completion of the operation, although this may be delayed six hours apparently without resultant ureteral or renal injury.

The technical results of this procedure may best be appreciated by a review of the experimental series tabulated herewith.

The following points with reference to Tables 1 and 2 are noteworthy:

1. The results of the preceding operations are operative only, for none of the animals received postoperative surgical attention.
2. Plus physiologic caudad ureteral resistance is manifested first by dilatation of the cephalad end of the ureter.
3. Continued incomplete ureteral obstruction leads to a dilatation of the second and third portions of the ureter and a dilatation of the renal pelvis.
4. Direct ureterosigmoidal entrance is more obstructive than the oblique entrance and the more oblique (from 1 to 2 cm.) the less that obstruction.

CONCLUSIONS

1. Ureterosigmoidal plastics are tedious for the operator and unsafe for the patient.
2. Operations in which the caudad ends of the ureters are allowed to protrude freely or fixedly within the sigmoid are meritorious in so far as the intramural portions of the ureters are unobstructed. Time spent in elaborating the terminal relations of the ureters is therefore valueless.
3. Oblique entrance from 1.5 to 2 cm. and the least foreign substance including blood and injured tissues are conducive to the least reactive inflammatory occlusion of the intramural portions of the ureters. These are most conveniently accomplished by the needle and ligature.

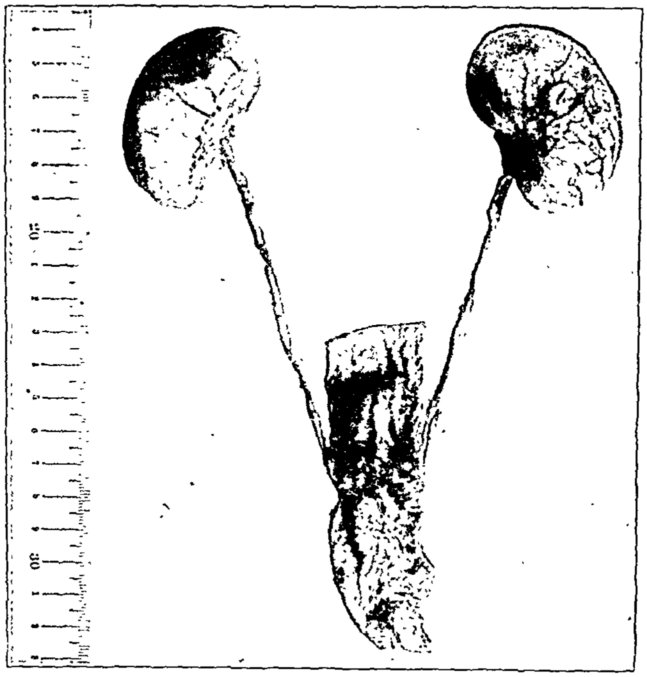

Fig. 5 (Dog 199 B 2).—Left kidney with foci of infection and right kidney normal fourteen days after transplantation of left ureter perpendicularly and right ureter obliquely for 2 cm. into sigmoid. Note sacculation of sigmoid with caudad ends of ureter firmly embedded in its mesenteric wall.

resistance in the muscular fibers of the rectum. Coffey[9] called his enteric implantation of the ureter "physiologic," while simulating the anatomy of the ureterovesical termination. The latter method has been followed by C. Mayo[12] in four cases recently reported by him. It seems to me, however, that the physiology of the ureter has for the greater part been disregarded, for it is believed at the present day that the ureterovesical valve is negligible physiologically. This dissimilarity between the pressure conditions of the intestinal tube and the closed urinary bladder further emphasizes the impertinence of a vesical ureteral termination in the bowel.

A further objection to all the operations to date is appropriately described by Matas,[6] thus:

> The operator who cuts off both ureters from the bladder and transplants them into the colon, must experience a certain and unavoidable anxiety—an anxiety that only further experience will overcome, that is *born of the feeling that he has burned his ship behind him and has staked all his patient's chances, all his hopes, in the hazard of the game.* It is the utter hopelessness of remedying the evil that must make any conscientious operator vacillate many times over before deciding to embark on so perilous an undertaking.

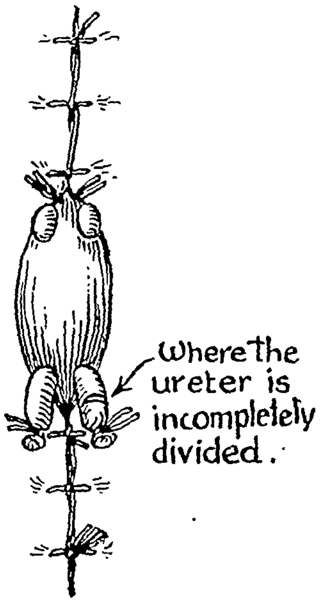

Fig. 4.—Distended ureteral ends.

A number of salient physiologic facts were brought out by our laboratory studies during the past two years. It was determined by Draper and Braasch[13] at the Mayo Clinic in 1911 that the ureterovesical valves may be destroyed in the presence of purulent cystitis without probable kidney infection. It was evidently probable from the studies[14] presented at Atlantic City in June, 1914, that of the two factors, *namely, the ureteral peristalsis and the mechanism of the ureterovesical valve, the peristaltic factor is often* the vitally important one in the determination of a possible renal infection. Furthermore, it was shown that when this ureteral function was seriously impaired, amounting virtually to a ureteral paralysis, and the ureterovesical valve function was left intact, hydronephrosis followed in 75 per cent. of cases.[15] The latter experiments have been repeated during the past fall with the following results:

> In Dogs 16 and 17, the infected vesical body had become a ureteral calculus. The expected results followed in a more accentuated form, but because of this new variant, these experiments have been omitted from consideration.
>
> Dogs 6 and 22 are negative.
>
> Of the remaining, 50 per cent. are hydronephrotic and 83⅓ per cent. are hydronephrotic or have dilated ureters. These results may be seen to compare favorably with those already referred to.

Hence, it appeared that an operation to have substantial functional value must, above all, involve the least possible traumatization of the ureter. Furthermore, it must be granted that some degree of traumatization is inevitable and that its peristaltic efficiency is proportionately impaired. Therefore the caudad resistance must be proportionately decreased if the ureter is expected to empty itself. For this reason, not only the resistance of a normal valve appeared too necessary by the removal of 4 inches of the left ureter during an operation for uterine cancer. The patient died of recurrence nine months later. I did not get the kidney but was informed that it functionated to the last without evidence of trouble. This was a trying case, as the ureter was dilated when the operation was done. My other case was one of exstrophy in a 2-year-old child. One ureter was implanted into the sigmoid Jan. 3, 1914; the other three months later. The child is now in perfect health, eighteen months after operation. Thus with Dr. Mayo's twelve and my three implantations we have fifteen ureterosigmoid implantations without death or ascending infection, as far as can be determined.

[15] Stewart and Barber: Hydronephrosis: An Experimental Study, Ann. Surg., December, 1914.

Dr. Bransford Lewis, St. Louis: I want to congratulate Dr. Braasch on the number of cases in which he has removed a stone from the ureter by cystoscopic methods—sixty-four cases. That is a good many more than I have done, but I am working up to that number gradually. For a number of years I have been advocating such a procedure before subjecting a patient to laparotomy. Some of you may be interested in the developments that have been made on that subject, and the several instruments that have been submitted by various authors to accomplish such a result. I am yet to be convinced that it has any legitimate danger. One contributor at the Pan-American Congress last week mentioned that he had, previous to operating, run in a stiff instrument of some sort and he had penetrated the ureter, and in operating he had been surprised to find out that it was outside of the ureter instead of inside. I do not think that comes within the scope of what might be expected. One should use instruments which are not of sufficient strength or stiffness to do that kind of damage.

Wappler of New York has lately constructed for me a ureteral dilator that has enabled me to go up into the ureter four or five inches, and by a special method I am permitted to dilate the narrowed part of the ureter. This is modelled like a Kollman urethral dilator, using two prongs instead of four, with a blunt end that is brought into contact with the stone, and then gradually, under the control of the operator on the outside, by means of the handle, the dilator is forcibly distended. In certain cases I have been able to get the stone down with this dilator when I had been unable to do so by other instruments and technic. This I consider an advance. Undoubtedly there have been several hundred cases that have been successfully reached in this way, which is sufficient evidence that these methods should be applied or resorted to before a kidney operation is had.

Dr. Frank Hinman, San Francisco: It seems to me that the significant feature in the analyses of these cases by Drs. Braasch and Cabot is the finding by one of 17 per cent. absence of blood and pus, and by the other of about 20 per cent. It is usual to consider absence of blood and pus after careful microscopic examination as strong presumptive evidence of the absence of stone. Both of these men also report a high percentage of failures of the Roentgen ray, considered by Dr. Cabot as being as high as 20 per cent. The symptoms, as shown by these analyses cannot be relied on for diagnosis. Therefore, we must have other means of diagnosis of stone in the ureter. The absence of blood and pus cannot be given much significance if absent in over 20 per cent. of cases, and the failure of the Roentgen ray in over 20 per cent. of cases means that a negative Roentgen ray does not eliminate the possibility of stone. The use of the wax-tipped catheter has not been mentioned, but it is the most accurate means of diagnosis at our command and should be used in every doubtful case. I wish to report a practical and simple method of application of the wax-tipped catheter in the male. A soft rubber urethral catheter, (No. 9 or 10 F.) which passes loosely through the operating telescope of the cystoscope, is cut off and slit up at one end so that when these ends are turned back over the telescope entrance they will hold the sheath in position with its distal end just beyond the lever of the instrument. The wax-tipped catheter may be passed through this rubber sheath without any danger of scratches from the lever or beak of the instrument, and this has the added advantage that several waxed tips may be passed at the one time and all withdrawn for examination without previously withdrawing the cystoscope. Functional study and pyelography may also be done at the one cystoscopy.

Dr. John W. Draper, New York: I am interested very much in the subject from the standpoint of experimental surgical physiology. I had the privilege of working with Dr. Braasch on the matter of this valve. The work was started by Dr. Lewis originally. I do feel that we showed conclusively by our experiments that the valve was of very little value. Its protective power against renal infection is perhaps about 10 per cent.; that of the physiologic integrity of the ureter itself, 90 per cent. I am therefore very much interested in listening to the discussion of the members of the section on this subject. Dr. Coffey's work is certainly a very important one and I congratulate him on its success. I feel that whatever the outcome of these studies may ultimately be, a great deal of credit is due to Dr. Coffey for the experimental work that he has done. Equal credit is also due for the more extensive experimental work that Dr. Barber has done.

I think, Mr. Chairman, a very important part of Dr. Barber's paper which may not have been made clear is the relationship which he draws between the neuromuscular tubes of the genito-urinary system and of the alimentary canal, in reference to dilation. Those matters in the future should receive more attention than they have in the past, and dilatations of the hollow viscera can be understood only through the interpretation given by comparative mammalian experimental studies. The close relationship between, a dilated stomach and a dilated kidney will thus become clear.

Dr. Granville MacGowan, Los Angeles: Dr. Cabot, what do you mean exactly when you say that your patients are not well after the operations?

Dr. Cabot: I mean they are not cured of their difficulties. A majority of the patients who were reported as well now have stone in the kidney.

Dr. MacGowan: Did you originally take all of the stones out of the kidney or have new stones formed?

Dr. Cabot: I have no data on that.

Dr. Martin Krotoszyner, San Francisco: In connection with Dr. Cabot's statement that in 14 per cent. of his cases of nephrolithiasis no blood or pus could be found on repeated and persistent urinalysis, I would like to ask if the search was made immediately or shortly after an attack of kidney colic? I have always looked on the findings of microscopic blood after an attack of renal colic as an important and, occasionally, the only guide to a correct diagnosis.

Dr. Hugh Cabot, Boston: Dr. Barber's work seems to me an important piece of experimental work on the question of the formation of a valve, and yet I do not believe that the creation of a valve will prove to be a matter of any importance.

I am thoroughly familiar with Dr. Coffey's work, which was based on a most ingenious conception, skilfully worked out. He has just commented on the fact that the common duct, and I believe also the ureter, was found dilated above the implantation when done by former methods, and he therefore concludes that this is satisfactory evidence of undue resistance at the intestinal end. With this conclusion I am unable to agree. We have, during the last four years, had a good many cases in which implantation of ureters was necessary and the most striking single fact has been the regularity with which dilatation of the ureter has occurred, even in the entire absence of stricture at the lower end. Dr. Barber's paper suggests to me that this dilatation is due not to obstruction, but to injury to the nerve supply of the ureter. We are dealing here with an active muscular organ and not a simple conducting tube. Its nerve supply is unquestionably segmental, and injury to this nerve supply is likely to be followed by paralytic dilatation. This paralytic dilatation will readily become an objectionable source of obstruction. That obstruction in some form is a factor of importance in causing renal infection may readily be admitted without assuming that it is the only or the most important factor. It is my present opinion that the infection takes place generally from the cut end of the ureter and by lymphatic channels, and that this source of infection, which was pointed out by Stewart and Swett, has been too little taken into consideration. I am interested in Dr. Coffey's conclusion based on his communication from C. H. Mayo to the effect that infection of the kidneys has not taken place in the cases in which his method was applied. In consideration of the great difficulty of drawing conclusions as to the integrity of the kidney in cases in which the urine is secreted into the bowel, and the well-known fact that extensive kidney infection may occur and exist without producing symptoms, one may be pardoned for being unwilling to accept this evidence as conclusive. We know that important grades of pyelonephritis may show their presence only by a slight trace of albumin in the urine and a persistent bacilluria. We are not furnished with evidence sufficient to warrant the opinion that these kidneys have remained free from infection.

Dr. George Lee Eaton, San Francisco: Mention has been made of the transplantation of the ureter into the appendix. I would like to make a statement in regard to the transplantation of the right ureter into the appendix which was reported to the San Francisco Urological Society some four years ago. I performed the operation of transplanting the ureter into the appendix, as it was impossible to transplant into the bladder, which was injured during a former operation. Up to four months ago the patient has shown no ill effects due to ascending infection, and to prove the kidney is functionating, the least diuretic in the way of water causes an immediate purgation.

Dr. W. F. Braasch, Rochester, Minn.: Dr. Barber deserves a great deal of credit for the work he has done in demonstrating certain facts concerning the physiology of the ureter. The outcome of the operation for ureteral transplantation depends, largely, on whether or not the kidney becomes infected. Renal infection will usually be the direct result of obstruction in the urinary drainage. If drainage from the kidney is obstructed, infection will follow. The degree of natural resistance will also be a factor in overcoming a slight interference with drainage. I believe that the success of Dr. Coffey's operation is due to the fact that the urinary drainage has not been interfered with. In regard to Dr. Cabot's paper, it is unfortunate that he has confused the consideration of stone in the kidney with that of stone in the ureter, since they may have widely different symptoms and pathology.

In regard to the number of stones found on either side, I believe that in a large series of cases it will be found practically equal. As far as the proportion of occurrence in the male and female is concerned, it is undoubtedly true that urinary lithiasis occurs much more frequently in the male. The same is true with the various forms of renal infection. I am under the impression that the similar relative proportion in lithiasis and renal infection is corroboratory of the fact that a like etiologic factor exists in both conditions.

Dr. Hiram R. Loux, Philadelphia: I was much gratified to hear the report of Dr. Coffey. It has an important bearing on the momentous question pertaining to conservatism in surgery. I believe that frequently one may save a kidney, whereas it is possible to sacrifice it unnecessarily. After the discussion this afternoon, and the reports of these cases, and the methods of transplantation, I think the tendency of this meeting is toward transplantation. I believe, however, that as Dr. Braasch just stated, it is a question of resistance added to the question of infection of the ureter as to whether the recovery is complete or whether we have an early infection higher up.

Dr. W. Howard Barber, New York: This brief paper on anastomosis has simply been a surgical study of the transplanting of the ureter physiologically. We all enjoyed Dr. Coffey's excellent description of his operation. It is interesting that Dr. Coffey secured better results when he made his anastomosis somewhat oblique after the manner suggested by the common bile duct entrance.

Last summer Dr. Braasch, at Atlantic City, commented on the care with which the Coffey operation was done, and contended that in that way the neuromuscular control of the ureter had been preserved. The importance of the neuromuscular apparatus of the ureter was brought out then by us and finds present agreement in the remarks of Drs. Cabot and Draper.

Dr. A. J. Crowell, Charlotte, N. C.: What percentage of stone formations in your series have returned, and what percentage followed with infection which caused you to claim they are not well?

Dr. Cabot: Of this 49 per cent., how many of them had stones and how many of them had other things?

Dr. Crowell: Yes.

Dr. Cabot: I could not be particularly accurate on that, because the report had to be based on the finding of shadows. The plates showed shadows which we believed to be due to stone, but we do not know they were due to stone. These were cases recently collected for investigation and none of the patients has been operated on.

In reply to Dr. Krotoszyner I will say that many of them were not examined immediately after an attack, for the reason that patients will not have an attack when you want them to. They come to the hospital and you keep them there, put them under a variety of conditions of diet and exercise, and yet they will not have an attack. Send them home and they will at once have one, especially if they live at a great distance. We cannot examine them always in the immediate period of an attack.

In regard to Dr. Braasch's discussion, I am entirely willing to accept his criticism. This would have been a more valuable study had it been divided, but it was not possible to do so. A good many of them were cases of both stone in the kidney and the ureter.

I am not at all in accord with the view expressed by Dr. Braasch in regard to the greater frequency of infection in the male than in the female. I believe that precisely the opposite is true, that renal infection is much more common in the female, but of lesser degree and severity. In the female child the occurrence of pyelonephritis, as compared with the male child, is ten to one. Take the frequency of pyelonephritis in cases of first pregnancy, and the number is very large in my part of the country. We have a large number of cases in women, much larger than at the same age in men. Many of these cases are comparatively transitory, and many of the women have comparatively little trouble for many years. I am not at all prepared to believe that infection of the kidney is more common in the male. I do not believe that infection is an important cause of stone formation. I am inclined to regard renal obstruction of some type as a very important factor.

Improvers of the Race.—There has been an increasing interest in the question of the improvement of the race during recent years. Unfortunately, discussion of the matter has not remained in the hands of competent persons, but pretty much every one who has a babbling tongue or who can scribble, and who either feels it his mission to remake the world, or who has discovered how easy it is to become famous via the cheap magazines, has taken part. Psychology and psychiatry are subjects that have a curious attraction for the eccentric, the borderland insane, the half educated, and the emotional, and as many people of these types have a ready tongue and pen, a great deal of harmful as well as harmless silly stuff has been printed. We in this country suffer more than some other parts of the world from self-appointed improvers of the machinery of the universe, because every man's opinion is as good as another's in a democracy, and . . . because the political and scientific paranoiacs, who seize every opportunity to be in the front of every popular movement, and sometimes for a time succeed, always have a large following.—Charles W. Burr, M.D.

FRACTURES

NEW IDEAS AND NEW INSTRUMENTS*

H. R. ALLEN, M.D.
Professor of Orthopedic Surgery, Indiana University School of Medicine
INDIANAPOLIS

It is fortunate that a paper on new surgical treatment of fractures does not imply that all fractures shall be treated by open surgical methods. However, it does imply correctly that neither the closed nor open methods are as efficient as they should be. Within a short time the entire subject of closed treatment will have to be rewritten on a selection of entirely different basic mechanical principles.

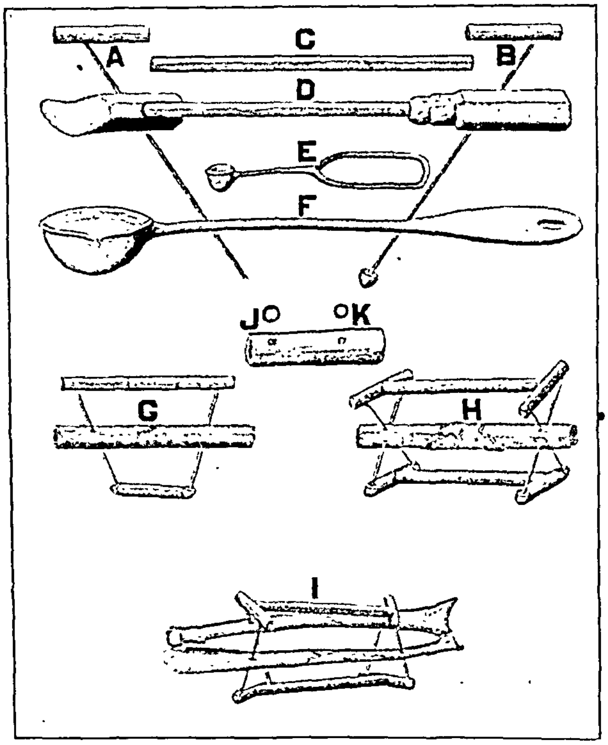

Fig. 1.—*A, B,* bone pins with low melting alloy handles (160 F.). The drill point on *B* has cast on it an alloy button used to couple it with another drill point. *C,* a bar of low melting alloy for joining drill handles in case they are not long enough to reach each other without such extensions. *E,* ladle for casting alloy buttons on points of drills. *F,* a large ladle for melting alloy over flame or in hot water. *J, K,* different shaped holes, *J* due to reciprocating movement of flat drill, *K* due to continuous rotation of any form of drill. *G,* diagrammatic scheme for holding fragments of broken bones in accurate reduction. The two pins do not lie in the same plane. Each represents a scheme for holding fractured ends by using constant normal distance rods. *I,* fracture of radius and ulna. Note the process of preserving normal length and proper separation of fragments. No rotation, angularity or overriding is permissible under this system.

The conventional methods still in practice, since the days of Columbus, when the world was flat, depend on most excellent mechanical principles. These principles, sound and unalterable as they are, happen to be absolutely inappropriate for the mission expected of them. Their absolute soundness does not guarantee their appropriateness any more than the unsoundness of ancient argument guaranteed for us a flat earth. Man alone is responsible for the misuse of judgment in selecting inappropriate ways and means.

In new open surgical treatment it is naturally consistent to find a composite mixture of modern sparkling ingenuity within the calcified shroud of St. Christopher. Surgical ingenuity is not efficient because of ingenuity alone. It must be coupled with additional qualities in order to be sufficient. A Lane plate for instance, involves a trace of ingenuity; but, in my opinion, to leave a foreign body permanently embedded in a wound borders on bad surgery, whether that permanent foreign body be a pair of forceps or a pair of spectacles or a bunch of screws, loose or penetrating the holes of a steel plate. To leave a foreign body permanently embedded in a wound is at least an unnecessary procedure.

Up to the present time we have seen outside and inside bone splints of various kinds. Those outside remain dry, those inside wet, of course. Now comes a new variety of amphibious appliances existing both inside and outside at the same time. There are several varieties A few will illustrate the generic qualities of all. They are protruding nails elevating, depressing and anchoring cleats, protruding wire loops thrown around bone and secured to an outside straight edge, and, lastly, the bone gimlet with its low melting alloy handle. All of these devices are amphibious, that is, they extend from bone out through soft tissues into the open air. They are all silver or silver plated, with polished smooth sides. After union occurs, they have served their purpose and are removed without secondary surgical operation. They do not remain as permanent foreign bodies. To install them, the length of incision and the amount of dissection about the bone is greatly reduced. They do not come in contact with the fracture zone. They do not compress periosteum

or bridge across fractured areas. They are applied remote from the fracture zone unless desired to traverse it. They are not inadjustable, but at all times provide excellent outside control over inside conditions, and up to the present time, no case of infection can be attributed to them, although in my hands and in the hands of others, they have passed through external pus areas without producing deep or internal infection.

To say that children and patients of all ages do not suffer or complain while wearing these transfixing or protruding devices would at first suggest straining a point in veracity; but, on second thought, you may correctly compare these devices to deep sutures. If your patients do not complain of pain from their deep sutures, they will not complain from these protruding devices, because, at the time of their application, all soft tissue strain is relieved by overstretching or by insignificant incision. Furthermore, a suture has a compression and constriction element, which is here absent. From the foregoing suggestions and other

or the first case of infection, it may
call that, of all safe drainage material,
surpasses silver, and of all known methods
ainage, none excels through-and-through drain-
The combination of through-and-through silver
drainage may play a very important part in the absence of infection.

The use of protruding nails, cleats, etc., and wire loops secured to outside straight edges is self-evident after a moment's observation of the illustrations, Figures 4, 5 and 6. My practice with the wire loops is to use soft steel wire silver plated. The loop passing around the bone should never constrict the bone or the periosteum. It should have as near 180 degrees bearing on the bone as possible. As it enters the skin it approaches the bone at a tangent, passes 180 degrees around the bone, and then leaves as a tangent out through the soft tissues and skin to its outside straight edge attachment. In case more bearing is essential, at least 60 degrees of unrestricted circumference should be provided. In this event the wires must be twisted five times on each other to the right. Then in order to remove them, after bone union occurs, they are to be untwisted five times to the left, and the loop pulled out. (Fig. 5 *A, B, C, D, E, F*). In employing silver plated wire nails, one should be sure to use very long thin "finishing nails." The heads protrude far enough so that a good hold may be taken on them with extracting forceps, as they sometimes become tightly *embedded*. (Fig. 4 *B*).

The flat silver plated drills with their alloy handles may be used with or without an exploratory incision over the zone of fracture. Usually, I make the incision in order to secure an absolute and accurate reduction, and I should announce here that absolutely accurate maintenance of reduction is possible with this system of treatment. The bones are brought into absolute reduction, the bone adjusting lever being used if necessary. (Fig. 2 *D, E, F, G*.) The exploratory incision provides digital and ocular inspection. The bone pins are passed through the bone an inch or so on both sides of the fracture zone. While the reduction is held absolute and accurate, the low melting handles are brought into line, touched with the soldering iron and the ends are fused together. The operator releases his hold on the bones, and they remain locked in absolute reduction as if by magic. An alloy button is then cast on the end of each drill, and a segment of the alloy fused to each button, thus affording additional stability in locking the broken ends tight together. The exploratory wound is sutured, and a wet antiseptic dressing is applied over it and around the projection of each transfixing pin. It must be remembered that no two pins should lie in the same plane. It is difficult to put them parallel and in the same plane. Fortunately, the easy unparallel way is the correct way, and the more the drills depart from parallelism, the more secure this system becomes. If a carpenter desires to make a studding stand erect on a floor he does not drive all of his nails parallel or in parallel planes. He "staggers" or "toe nails" the nails into place, and the studding "stays put." A Lane plate and all similar devices depend on parallelism of screws. (Fig. 2 *A, B*). Furthermore, the screws have only from 1/16 to 3/16 inch bearing for their threads. The long end of the screw projects into the bone canal or fragile cancellous tissue, and is totally an absolutely devoid of function. The transfixing pi have bearings in both layers of hard bone, which a more remote from each other than the diameter of the bone. This is due to the fact that the drills pass obliquely through the bones.

Every man who has bored round holes in bones for wires or screws or nails knows from his roentgenograms and secondary operations that in about a fortnight these round holes have become oval or egg shaped. With a Lane plate there is no chance to take up the slack. With the transfixing pins one has absolute outside control over inside conditions and can take up as much slack or correct as much rotation as desired without a secondary surgical operation. One merely melts or cuts the handles apart on one side, separates or rotates them as one likes, and then fills in the gap between the handles with a drop or more of the low melting alloy. When the Roentgen ray shows bone union, one is at liberty to melt the alloy off of both ends of the drill rods, paint the rods with iodin, and allow them to dry thoroughly, when they will be easily pulled through the holes originally made. These holes, it must be remembered, form a free working hole through both hard and soft tissues. Gentle traction with the fingers is sufficient to extract them. The alloy melts at about 160 F., so that warm water will melt it; or if one is in a hurry, the knife-bladed soldering iron may be used. (Fig. 1 *D*.) Twist drills and continuous rotation with flat drills should not be used; they should be sent through the bones with a reciprocating movement passing through a working arc of about 165 degrees and not through as much as 180 degrees (Fig. 1 *J, K*). In this way two things happen: the nerves and blood vessels are pushed aside, and the hole through the bone is not a complete circle, but has a pair of internal opposed bone ridges which guarantee a tight fit against the drill shaft as shown in the illustration. A twist drill with its uninterrupted rotation not only drills a round hole, but also will wind up and extract loose soft tissues on itself.

Concerning bone grafts, I desire to present two methods. One is known as the telescopic bone graft and the other as double opposed wedge graft, which automatically locks itself and the fractured bones together (Fig. 3 *M, N*).

If a portion of a shaft of a long bone is absent, the gap may be bridged as follows: A deep canal or tunnel is drilled into the axis of the longer fragment, and a shorter canal into the shorter fragment; a long dowel pin is turned up to fit the bored canal, the dowel pin slipped down into the long canal, the two canals brought into line and the dowel pin worked toward and well into the short canal (Fig. 3 *M*). The short end is pinned with a transverse bone pin, and then when the broken bone is pulled to its normal length, the long telescoped end is secured with another transverse bone pin as shown in Figure 3 *M*. If desired, the dowel pin need not be circular, but may have a flat side with periosteum still intact. The ends of the periosteum may be stripped up and put in contact with the periosteum at each end of the fracture.

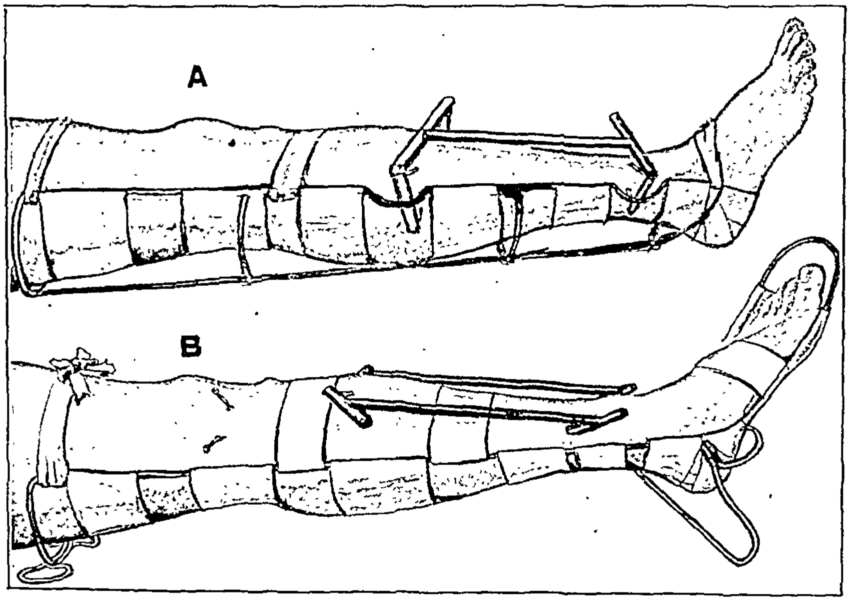

Fig. 4.—*A*, wire and adhesive plaster brace used in connection with bone pins and constant distance rods in treating a shattered tibia and fibula. *B*, use of protruding nails in securing broken off portion of the tibial head; also constant distance rods and bone pins with low melting alloy handles. Note that the wire brace among other duties keeps the bed clothes from resting on the foot and also prevents the leg from rolling.

Another interesting bone graft is the double opposed wedge graft. It involves the use of a wedge-cutting saw, like the one presented, which has two different ways of cutting wedges, as shown in Figure 3 *A, B, C, D, E, F, G*. The male wedge and the female, or the positive and negative wedges, must be accurately cut. The ends of the wedges are cut with opposing wedges or bevels. The broken bone is pulled far enough apart to let the wedge drop into place (Fig. 3 *N*). The traction is then released, the soft parts drag the bone fragments tight into place, and by the double opposed keystone or opposed wedges the bones are locked in place, requiring no bone pins to hold them together. Before attempting this operation, one must become adept in accurate bone cutting. In this form of graft the periosteum may be left intact throughout the entire length and breadth of the graft.

The last method of bone cleating may have some novel features of unusual interest. It consists of a process of welding any desired metal on a bone in the form of a cleat or key or wedge or "C" clamp or any pattern desired. The metal to be used is atomized and the minute particles of metal are impelled against the recipient area until they are welded cold on each other to any desired thickness. The specimens presented to you show the bone is not burned. The periosteum of one bone is still intact, although it is scraped away from the other bone. The pasteboard calling card has metal welded on it, although the card is not burned (Fig. 2 *H*). Around one of the bones a German silver band is welded; about the other is a band first of steel, then copper and then brass; then on this practically any other metal may be welded on cold. Interesting as this may be, I cannot recommend its use, because any foreign body permanently left in a wound is, I believe, not only unnecessary but borders very closely on bad surgery.

Concerning the splints used in connection with all of these new methods, I cannot refrain from making an appealing request. Please use wire and adhesive plaster braces or splints. They are simple, light, strong, sanitary, cheap, durable, adjustable and betray the first requisite of new fracture work. If a man is not mechanic enough to make these little things, he is unfit to attempt accurate fracture work. When you go home buy some tinned steel wire and practice making them. They do not hide the work you should be proud of, but leave it always open for free examination and inspection. You can treat other conditions aside from fractures with wire and adhesive plaster appliances. They are appropriate to many deformities and make excellent framework over which gauze may be stretched in employing open air treatment. The gauze is kept from the wound or lesion and the gauze is a filter against dust. When you learn to use them, no one can lead you back to plaster of Paris. In the new treatment of fractures I most certainly include these new wire braces among the new ideas and new instruments.

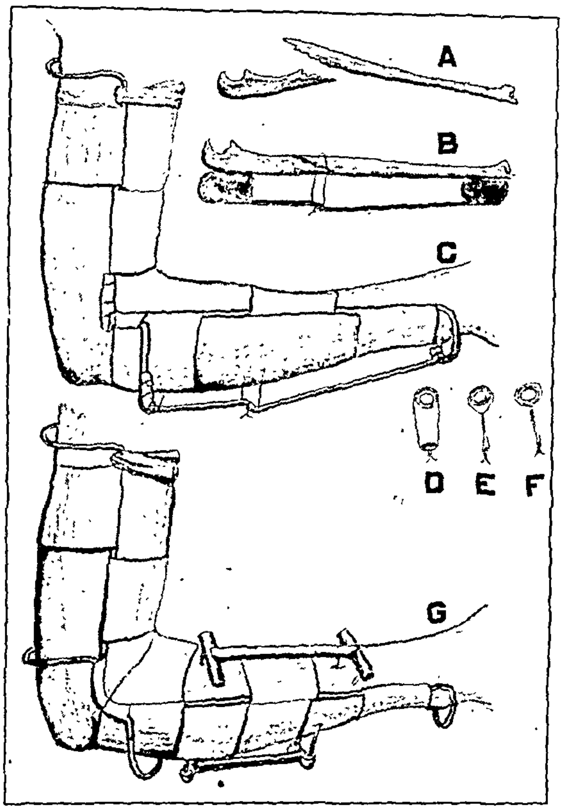

Fig. 5.—*C*, wire and adhesive plaster braces used in connection with the wire loop method of treating fractures. *A*, *B*, conditions of fracture and the three lever points essential to fixation. *G*, wire brace and bone pins employed in fracture of both radius and ulna.

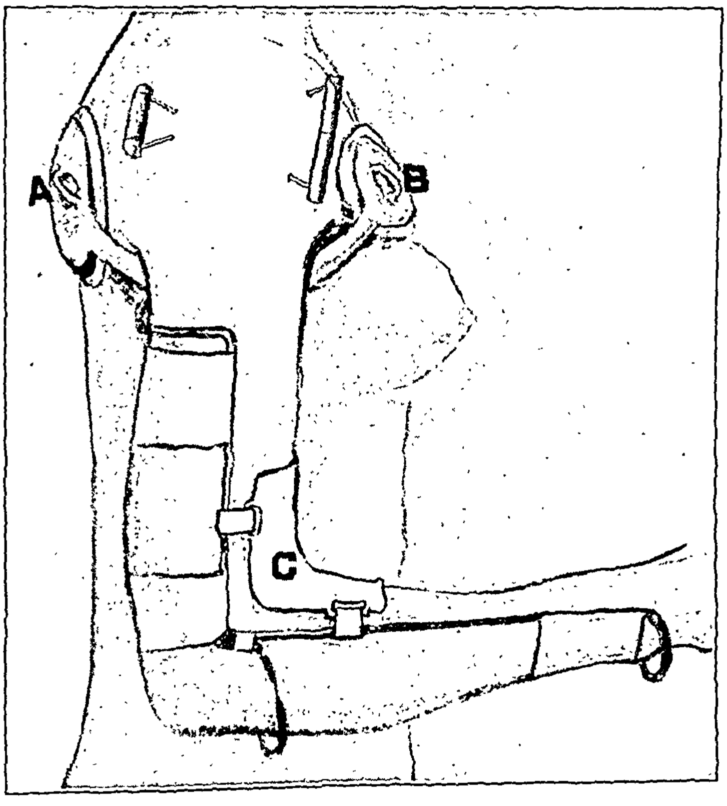

Fig. 6.—Brace and bone pins for fracture of head of the humerus. The pins prevent rotation of the fractured head on shaft. Absolute and accurate maintenance of reduction is possible by this method. The crutch under the arm and the anterior elbow plate provide fixed points for the application of fixation forces. In case the axilla is burned or from other causes cannot be used for superior fixation point, adhesive bandages upon the back, abdomen and side attached to loops *A* and *B* constitute a stable superior fixation base which may be depended on.

ABSTRACT OF DISCUSSION

Dr. P. C. H. Pahl, Los Angeles: I read an article by Steinman in which he said he produced traction on the tibia, fibula and I think also the femur by means of nails passed through the bones. It has occurred to me many times that there were cases of fracture of both tibia and fibula and of the femur in which it was very difficult to produce traction by the means of adhesive plaster. Sometimes the adhesive plaster irritates, and sometimes the tissues are lacerated. When there are many fragments, bone grafts and Lane plates are out of the question; traction then is the only thing, and in order to gain this I have made what I have called a spine tractor—two thorns that go into the bone through little incisions, and then traction is applied. I have done this in twenty-one cases. I am very sorry to say that two of the patients subsequently died, although I did not personally have absolute control over them. It is possible to produce traction, and I have produced as much as 65 pounds in the beginning and gradually reduced this to twenty-five pounds, the treatment lasting for two months and a half. I did this in a Mexican who had a fractured femur, in the upper end, in which there were five fragments. Personally, I have not had the experience which warrants cutting down to the bone on a man who has five fragments in his femur. In this case I put the spines into the condyle of the femur, making the traction vertical, with the leg flexed. I have never been able to make traction vertical with the knee extended, but with the knee bent, it is possible to do so. The first traction was so much that the patient was lifted up in bed, and, of course, there was much lack of apposition, but finally the fragments came into proper position, and the man got a functional leg. What Dr. Allen says about positive fixation has also occurred to me. I have an instrument which I call a "multiple spine splint." I made one for the tibia. I place two spines on the lower end and two on the upper end of the fibula and tibia. I make, if necessary, a small incision over the fracture, reduce the fracture, and then tighten these four spines, or two sets of spines, which really make a bone vise. These cases were all satisfactory. I must say, however, that prejudice against them is very great, and in a municipal hospital where there are many men, it is almost impossible to use them.

Dr. H. M. Sherman, San Francisco: I was much impressed with one statement which Dr. Allen made, and that was the fact that he never got infection. Now a long time ago I began to nail the neck of the femur in fractures of that part of the skeleton, and it always became infected if the nail head was on the surface. Longer ago than that, Parkhill devised this scheme of fastening bones, but all the openings which passed through the skin became infected. The Lambotte scheme, and all the variations and modifications of that, where a drill point or a nail goes through the skin and then into the deeper tissues and remains there, always call for infection. We are now making what we call skeleton traction by a pin through the femur, instead of a Buck's apparatus, and it is a method by which we always get local infection. Dr. Allen says he puts those bits of wire pegs through an infected area into the deeper parts, and never gets an infection. I want him to tell us how he avoids infection, because if he will tell us that, he will put into our hands not only his own apparatus, ingenious as it may be, but he will give us the most important piece of information in his possession—one for which surgery is anxiously waiting—and we will all begin to look around for mechanical ideas and will be able to take care of fractures as easily as he.

Dr. Allen cites the fact, which is perfectly well known, that a screw in a bone bearing weight always causes a necrosis of the part of the bone against which it is pressing so that the holes become oval; and they become even more than that; they become quite large places. I put two screws in a dog's bone, setting them in the bone very firmly, about an inch apart, and then put a little elastic band around them and sutured the wound. The wound healed and in about a month I opened it and found that both of those screws had been pulled out of the bone by that little elastic. The pull of a little piece of india rubber was sufficient to make a round hole oval, and then to pull the screw out of this oval hole. Does not Dr. Allen get the same kind of pressure, absolutely, with the wire pegs which he puts through the bones, so that we can expect the same results under these circumstances? These are things I should very much like to have Dr. Allen explain to us.

Dr. H. R. Allen, Indianapolis: Dr. Pahl suggests the inadvisability of cutting down on a femur fractured in five places. Such a case should be treated by the application of fixation forces for fixation purposes. If any fragment remained uncontrollable under the closed method it could be cut down on and treated by the open application of fixation forces for fixation purposes. We must not delude ourselves by thinking that the irregular muscle force is in any sense a balance or counterpart of a constant force. The application of a constant force through a weight and pulley implies motion of parts desired to be kept quiet and fixed. The application for fixation forces implied absence of motion and the presence of fixation. To oppose the constant force of gravity by the irregular force of muscle necessarily leaves a plus or minus balance of force resulting in motion. Fixation forces are not concerned with motion. Dr. Sherman presents two good points: one refers to the application of a rubber band and the other to the possibilities of infection. A rubber band, of course, while inactive is inert, but during activity it represents a constant force and must be dealt with according to its own generic qualities of constancy. Concerning infection, or rather the absence of it, I am inclined to believe that my good fortune in this regard has been influenced possibly by the technic employed. The operation field should be scrubbed with soap and water, rinsed with mercuric chlorid solution, then washed with alcohol and painted with iodin, which is removed with ether. Every instrument, in fact everything, is wet with mercury solution while it is near or in contact with the wound. Each wound is thoroughly irrigated with mercuric chlorid solution, and after suturing with mercuric chlorid soaked silk a wet mercuric chlorid dressing is applied and maintained as a permanent dressing. I believe in the use of mercuric chlorid. I also believe in through and through silver drainage.

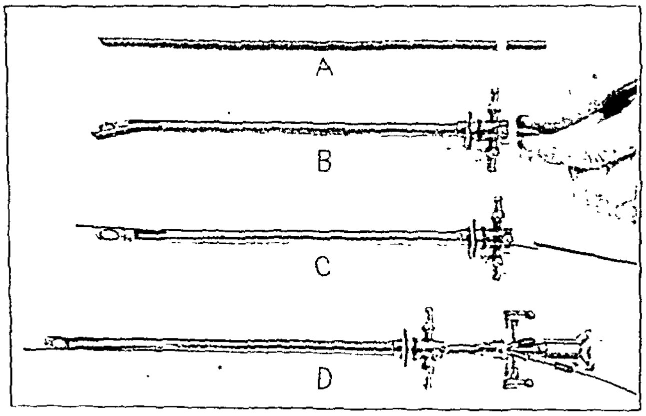

Fig. 1.—*A*. The rubber catheter with distal end cut on an angle of 90 degrees to allow its easy escape from the fenestra of the cystoscope. *B*. Rubber sheath introduced into the outer sheath of the cystoscope and rotated between the fingers to allow its escape from the fenestra. *C*. Wax tip bougie or catheter which has been introduced into the instrument through the protective rubber sheath and held in position while this sheath has been pulled out from around it. *D*. Threading the catheterizing barrel onto the wax tip catheter.

What Is Good Literature?—Unless an author takes the material on which he writes out of his own head, that is to say, from his own observation, he is not worth reading.—Schopenhauer.

I. A NEW METHOD OF PASSING THE WAX TIP

II. MODIFICATION OF THE TECHNIC OF PASSING THE WAX TIP*

BEN R. KIRKENDALL, M.D.
COLUMBUS, OHIO

I. A NEW METHOD OF PASSING THE WAX TIP

In 1894, Howard A. Kelly introduced the wax tip catheter method of diagnosis of ureteral calculi in the female through the open cystoscope. Since then many other observers have attested its value:

First, the wax tip will diagnose ureteral calculi unaided. Second, in conjunction with roentgenoscopy, it will rule out or make positive a shadow in the line of the ureter.

Third, it will diagnose ureteral calculi which have been entirely missed by the Roentgen rays.

Fourth, the gynecologists for several years have been able to locate the site of ureteral calculi by passing a ureteral catheter, with a series of wax bulbs, through the open cystoscope.

Three years ago, Burton Harris devised a method for the use of the wax tip with the male catheterizing cystoscope by passing the wax tip into a filled bladder and threading the cystoscope containing its catheterizing barrel onto the catheter, through the urethra into the bladder.

This procedure excites more pain and produces more trauma than an ordinary cystoscopy by the increased dilatation of the urethra and the liability of the open fenestra of the instrument to scrape or tear the mucous membrane. It requires a separate instrumentation for the introduction of the wax tip, and also requires the removal of the cystoscope before the wax tip can be withdrawn for examination.

A much simpler method with more possibilities is proposed as follows: An ordinary catheterizing cystoscope is used. The lumen of the outer sheath is lined with a loose fitting rubber tube to protect the wax tip in its passage into and out of the bladder. The tube is made from a soft rubber catheter, about a 16 or 18 F. The eye end of the catheter is cut off on a slant or angle of about 90 degrees. On this slant-cut end depends the ease of the following manipulations. The catheter, this end first, is passed into the cystoscopic sheath and out through its fenestra to the beak of the instrument.

The other end of the catheter is cut off an inch from the proximal end of the cystoscope, and it is allowed to protrude for a finger hold.

We are now making what we call skeleton traction by a pin through the femur, instead of a Buck's apparatus, and it is a method by which we always get local infection. Dr. Allen says he puts those bits of wire pegs through an infected area into the deeper parts, and never gets an infection. I want him to tell us how he avoids infection, because if he will tell us that, he will put into our hands not only his own apparatus, ingenious as it may be, but he will give us the most important piece of information in his possession—one for which sheath close to the ureteral orifice, and obviates raising the elevator to a greater angle, which would decrease the lumen of the catheter sheath. The small catheter sleeve is removed before the wax bulbs appear outside the instrument. Control wax-prepared bougies may be passed if deemed advisable.

On examination of the prepared bougie after its passage, it is obvious that if there is a scratch on the No. 1 wax tip and none on any of the bulbs, the calculus must lie in or near the renal pelvis. Likewise if all of the wax bulbs are scratched, the stone is within the ureter at or near its vesical orifice; while if some of the proximal bulbs escape the marring, the last one scratched locates the calculus at a corresponding point in the ureter.

This method is equally adaptable for use in the two sexes, and assures the accurate location of ureteral calculus without the aid of the Roentgen ray and will often diagnose calculi missed by it. The bougie being impenetrable to the Roentgen ray, a roentgenogram may be taken with it in place, if thought advisable. This will show the relation of the ureter to any suspicious extra-ureteral shadow.

LEUKEMIA—AN INFECTION?

WITH REPORT OF CASES [*]

RAY LYMAN WILBUR, M.D.
SAN FRANCISCO

Morphologic studies are so interesting and apparently definite that it is not surprising that there has been a tendency among medical men to spend an undue amount of time on this phase of the leukemias rather than on the more vital one of etiology.

The breaking down of the artificial borderlines of distinction between the leukemias, the leukemic changes in the blood in the presence of established infections,[1] and the variability in the findings in different patients and at different times in the same patient as shown by the report of many writers, notably Klieneberger,[2] Stein,[3] Marchet and Rieux,[4] Reschad and Schilling,[5] Moreschi,[6] Ghedini,[7] Strauch,[8] Morawitz,[9] Warren[10] and Paltauf,[11] have diverted attention more particularly of late to the cause of the leukemic process. We now hesitate to go much beyond the word "leukemia" or "leukemic state" in making a diagnosis, perhaps adding to it "lymphatic type," or "myelogenous type," as the case may be.

While the conception of leukemia as a neoplasm, fathered by Banti and others, is still extant mainly because of the tendency of enlarged glands during overgrowth to involve other structures, and the idea of Naegeli[12] that leukemia is a distinct entity rather than a neoplasm or infection has been welcomed by a few, the general trend of medical opinion seems to be more and more to regard the leukemic process as the result of an infection or a secondary toxicosis of particular parts of the body, primarily the bone marrow, spleen and lymphatic structures. This infection may be due to some one unknown organism, but present information makes it more probable that it can be caused by several different ones when the conditions are favorable. Chronicity of infection with low virulence, but with the liability to acute exacerbations, bone-marrow involvement, one infection preparing the soil for the next, are outstanding features of many of the published reports. Lymphocytosis as distinguished from leukemia has led to confusion, and borderlines are hard to draw. The recovery of patients with marked lymphocytosis or leukemia, as the case may be, has been reported by a number of observers, notably Cabot,[13] Jackson and Smith,[14] Türk,[15] and here in California we have had such patients under observation. Such high lymphocyte counts as those noted in typhoid (Herz,[16]), pneumonia and other ordinary infections (Steven,[17] Cabot,[13] Austrian,[18] Hirschfeld and Kothe[19]), and the leukemic blood changes following bone injury—fracture—and definite bone infection (Simon,[20] Herz,[16] Ward,[21] Stursberg[22]) are more than suggestive. Certainly too little attention has been given to the bone marrow as a nidus for all sorts of infection. The selective action for certain portions of bone marrow shown by the tubercle bacillus as brought out by Ely,[23] together with the lymphocytosis characteristic of that infection, is worthy of note.

Early investigators (Fraenkel, Ebstein) noted the striking resemblance of leukemias to infections, particularly the acute leukemias with fever, hemorrhages, skin lesions, splenic tumor and asthenia. Patients with the type dealt with by McCrae,[24] Lüdke,[25] Hirschfeld and Dünner,[26] Beltz,[27] Strauch,[28] and Nanta and Loubet,[29] are hard to understand on any other basis. Animal (Lüdke[30]) and chicken leukemia (Ellermann,[31] Ellermann and Bang[32]), the passage of the latter through a series of animals, and the apparent leukemic change in the blood of the fowl after inoculation with that from a human leukemic patient (Wiczkowski[33]) have excited much interest. Other inoculation experiments (Sternberg,[34] Fraenkel and Hatluch[35]), the possible contagiousness of the disease as indicated by Obrastzow's patient, the familial character noted at times (Barrenscheen,[36]) and its occurrence in a baby a few days old with a right-sided endocarditis (Pollmann[37]), and the early leukocytosis observed in a number of cases, all indicate infection. Numerous organisms have been described as occurring in the blood or tissues, the seat of leukemic changes. Among these, streptococci have been reported a number of times (Nanta and Loubet,[29] Jochmann,[38] Ziegler and Jochmann,[39] W. Erb, Jr.,[40] Churchill,[41] Sternberg,[34] *Gorjaew,[42] Marchet and Rieux,[43] Stursberg[22]) and* also Auer's bodies (Much and Hegler,[44] E. Fraenkel and Hatluch[35] (quoted by Arndt), Ottenburg,[45] von Domarus[46]). Tubercle bacilli (Nanta[47]), corynebacterium (Steele,[48] Simon and Judd[49]), staphylococci (Herz[16]) and various mixed organisms (Lavenson[50]). Some of these may well be secondary and some, like corynebacterium, are probably common enough in various dead body tissues not to be of well-defined significance. Besides, the question of primary and secondary infection is a most confusing one in this connection (Ward,[21] Neutra[51]). The development of aleukemia in leukemia under the influence of intercurrent disease, pneumonia, diphtheria, etc., is as puzzling as the leukemic states noted in defininte sepsis. The relationship to the status lymphaticus has been considered of much importance (Barrenscheen,[36] Citron[52]) in determining the leukemic reaction to possible infection. Blood-forming tissues, when infected, react in peculiar and as yet imperfectly determined ways. Sternberg has called attention to the frequency of myelocytosis in the course of various infections. Intestinal infections (Oppenheim,[53] Peacock[54]), tonsillar foci (Gilbert and Weil[55]), and the selective action of certain infections for bone marrow present features requiring careful analysis and study.

1. The explanation given by Döhrer and Pappenheim (Folia haemat., 1913, xvi, 145) that this is a special tendency to leukemia on the part of the blood-producing tissues, or a leukemoid reaction of the blood during sepsis (*"einer besonderen leukämischen Prädisposition der hämopoetischen Gewebe,"* or "leukämoide Blutreaktion bei Sepsis") seems inadequate.

In order to indicate some of the problems involved, and to emphasize that leukemia, although most variable, can readily be explained as due to an infection, the following three selected case histories are of interest:

CASE REPORTS

Case 1.—*Acute leukemia.* (Medical Clinic, Stanford Medical School.) April 2, 1913, H. H., an American office boy, aged 17, complained of swelling of the glands of the neck and slight cough. The family history was excellent. General health had always been satisfactory except for measles, whooping cough and mumps. Patient had had frequent toothache with swelling, the last time a year ago. Three weeks and a half ago he had pain in the upper part of the chest and swelling in the lower part of the neck, and later enlargement of the glands under the jaw and in the right groin. He noticed that he would spit up a lot of mucus, but no blood, and that his face would be puffed up in the morning, but would go down during the day. The wrists also were slightly swollen and tender. He had had some early morning sweats.

The patient was a well-built and well-nourished boy of good color. Except for the enlarged glands noted in the history, some puffiness about the eyes, hypertrophy of the tonsils and the evident involvement of the upper mediastinum with enlarged glands, no abnormalities were noted.

The blood examinations were as follows:

	April 2, 1913	April 7, 1913
Hemoglobin	80%	90%
Red blood corpuscles	4,850,000	4,980,000
White blood corpuscles	8,800	8,900
Polymorphonuclears	41%	48%
Lymphocytes	54%	45%
Large mononuclears	—	5%
Eosinophils	1%	—
Basophils	4%	2%

(The lymphocytes were mostly large granular forms.)

April 8, 1913, patient was vaccinated because of previous exposure to smallpox.

April 10, a clinical diagnosis of lymphosarcoma was made, and a posterior cervical gland was removed for microscopic diagnosis. The sections showed moderate hyperplasia of lymphadenoid tissue, moderate increase in fibrous tissue which in places showed marked thickening and hyaline change. No evidence of tumor found. Chronic lymphadenitis (Dr. E. C. Dickson).

April 15, although patient seemed to feel well, the blood counts were as follows:

	April 15	April 18	April 19 (Differ. Count*)	April 28
White blood corpuscles	252,000	233,600		440,000
Polymorphonuclears	6%	—	5.5%	2%
Lymphocytes	94%	—	86.0%	97%
Large mononuclears				1%
Myelocytes (fully developed)			1.0%	
Lymphoidocytes			2.0%	
"Kern Schatten"			5.0%	
Eosinophils			0.5%	
Red blood corpuscles				3,925,000
Hemoglobin				66%

* The great majority of the lymphocytes were from 6 to 8 microns in diameter, but a few microlymphocytes were present, and a large number of macrolymphocytes.

Degenerative changes were present in a large number of the cells—vacuolization and karyokinesis.

A small percentage of the large nongranular cells classed by Pappenheim as lymphoidocytes were found.

No myeloblasts or intermediary myelocytes were found, and the fully developed myelocytes or propolymorphs found were probably due to secondary bone-marrow irritation. No nucleated reds were found. (Dr. T. Addis.)

The patient was given Fowler's solution and Roentgen-ray exposures.

May 3, patient began to bleed freely from the nose and throat, the blood coming from about the uvula and the tonsils. There was a dull pain noted in the region of the spleen. Liver and spleen were both found to be enlarged and sensitive. There was hemorrhagic ecchymosis about the left upper and lower eyelid. Petechiae were noted in the pharynx and about the tonsils. The glands in the neck were distinctly smaller in size. Patient was free from pain, but felt weak and sleepy. He gradually became more restless and sleepless. Temperature ranged between 97 and 100.6 F. After two days of a comatose condition, patient died, May 15.

May 6, blood count was as follows: white blood corpuscles, 514,000; polymorphonuclears, 2 per cent.; lymphocytes, 98 per cent.

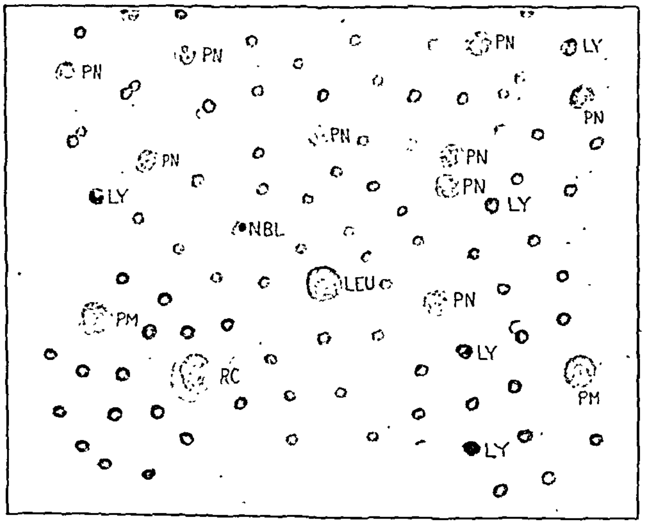

Fig. 1.—Blood, Case 3. Leukemia, myelogenous type, and anemia, pernicious type (?). *PN*, Polynuclear neutrophil; *LY*, lymphocyte; *LEU*, leukoblast; *RC*, Rieder cell; *PM*, promyelocyte; *NBL*, normoblast.

The details of the necropsy record are not available, but a marked enlargement of the mediastinal lymph glands was found and typical leukemic changes elsewhere.

Case 2.—*Acute leukemia.* (Stanford Medical Clinic; Lane Hospital.) C. F., Italian laborer, aged 38, was admitted March 3, 1915, complaining of weakness and loss of appetite. Family history unimportant. General health always good. Smallpox when 12 years of age. Never had cough or respiratory disturbance. Denied venereal infection. Drank wine with meals.

Three and one-half months ago (about Nov. 15, 1914), he began to feel weak and to lose appetite. Thought he had some fever, coughed a little, and noted small amount of blood in the sputum, and sweat considerably at night. About one month ago he consulted a doctor, who told him he had tuberculosis. Since that time cough had almost ceased, but weakness and loss of weight had continued. Had noticed increased thirst and urination. Four days ago he noted marked redness of right eyeball and surrounding tissues, occurring without trauma and without pain.

Examination on admission showed an emaciated man lying flat in bed, somewhat dyspneic. Color very pale. Marked visible pulsation of tortuous temporals. Extensive hemorrhage into right sclera and eyelids. Small ecchymoses in left sclera. Marked pulsation of carotids. Over right sternoclavicular joint was a small hard nodule, not tender, slightly movable. Percussion dulness over manubrium, extending slightly more to right than to left. Heart dulness increased slightly to right and left. Systolic murmur at apex, not transmitted. Slight abdominal rigidity. Spleen felt 5 cm. below costal margin. Slight pitting edema of ankles. Moderate enlargement of epitrochlears, axillary and inguinal nodes. Small areas of old hemorrhage scattered over skin of trunk. Temperature, 102.4 F.; pulse, 108.

Laboratory Reports.—Urine: Specific gravity, 1.015. Trace of albumin. No casts. Very few leukocytes and red cells. Blood: Red blood corpuscles, 1,123,000; white blood corpuscles, 199,600: 90 per cent. lymphocytes; 10 per cent. degenerated. Sputum: Small amount of blood. No tubercle bacilli. Stool: Occult blood present. Wassermann negative. Blood culture negative. Roentgenoscopy revealed enlarged mediastinal shadow and heart.

Course.—Temperature from 99 to 103 F. during first nine days. Fowler's solution, 5 minims, three times a day, was given. White count: March 4, 253,000; March 5, 117,000; March 7, 160,000; March 8, 81,000; March 10, 60,000. Hemorrhage into lids gradually cleared up, and that in sclera became much less. March 9, patient had hemorrhage from nose. March 10, 10 c.c. of wife's blood were given intravenously. Temperature fell to subnormal, and remained there until within a few hours of death, when it rose to 103.4 F.

Diagnosis.—Acute leukemia (lymphatic type); mediastinal glands especially involved.

Necropsy.—The principal items of interest in the necropsy, which was performed by Prof. William Ophüls, were as follows:

Smears and Cultures.—Smear of marrow of rib: Very many lymphocytic cells from two to three times diameter of red blood cells, many nucleated reds (normoblasts), moderate number of neutrophilic myelocytes, small amount of hematogenous pigment. *No bacteria or other parasites found in deeply stained Giemsa specimen in spite of careful study with mechanical stage.*

Smear of marrow vertebra.—Even fewer neutrophilic, eosinophilic and basophilic myelocytes. The rest of the cells have round nuclei of varying size, a very delicate finely granular protoplasm, the granules staining mostly blue with Giemsa, few of the very fine granules more reddish. Same cells but not quite so large in smear of rib.

Culture of mediastinal tumor; no growth.

Spleen: Many similar cells, few neutrophilic myelocytes, *few diplococci.*

Culture: *Many small colonies of diplostreptococci.*

Pericardium over tumor: Many endothelial cells, many degenerated vacuolated cells, *no bacteria.*

Retroperitoneal lymph gland: Many ordinary lymphocytes, few larger cells, no bacteria.

Liver: Many larger and smaller cells like those in bone marrow, few neutrophilic myelocytes, no bacteria. Culture: No growth.

Lung: *Many diplococci.*

Culture: *Many colonies of diplostreptococci.*

Kidney: Apparently nothing abnormal, no bacteria.

Left renal pelvis: The same.

Diagnosis.—Lymphosarcoma of anterior mediastinum. Leukemia, acute. Lungs, edema of, acute. Ganglion near sternoclavicular joint.

Tumor in mediastinum consists of framework of connective tissue in which are many large proliferative lymphocytes which show irregular distribution. Spleen shows pulp full of large lymphocytic cells. Enlarged lymph nodes: Marked hyperplasia of lymph adenoid tissue. Some show beginning leukemic infiltration of capsules.

Smears of blood taken before death show very large number of cells of lymphocytic type with large round, very deeply staining nuclei and narrow rim of hyaline protoplasm which stains distinctly blue and does not contain any granules. In some cells this protoplasm is arranged in knoblike pseudopods around the nucleus, few neutrophilic leukocytes and myelocytes, *one eosinophilic myelocyte.*

CASE 3.—*Leukemia, myelogenous type. Anemia, pernicious (?).* James W., English laborer, aged 60, came to the Stanford Medical Clinic, Dec. 13, 1913, complaining of headache and rheumatism. Family history unknown. Patient had had malaria three times, 1894, 1897, 1907. Denied typhoid and scarlet fever. Had syphilis in 1884. Had had poor teeth; eight or ten had to be taken out. Had always been troubled with frequent colds, but had never coughed up blood or had pain in the chest.

Two months ago, patient contracted a bad cold. This disappeared after two weeks, leaving a nasal catarrh, persistent headaches, pain and stiffness in the shoulders and left elbow which had remained constant. About a month ago a diffuse macular rash appeared on the back, chest, abdomen and thighs, blood-red in color. It gradually faded without producing itching or pain. Patient had lost in weight and appetite, had coughed up mucus free from blood and had had some pain in the precordial region.

Physical Examination.—The principal features of the examination were: a poorly nourished old man with pale skin and mucous membranes, some deafness, many missing teeth with some pyorrhea, some rigidity of the neck, well-developed chest with scattered areas of impairment and a few râles; some enlargement of the heart to the left with a systolic murmur but with no irregularity; peripheral vessels definitely sclerosed, and a chain of enlarged glands along the right brachial artery beginning above the internal condyle of the humerus. There was considerable limitation of movement of the right shoulder joint. On the skin were many sharply outlined elevated, indurated, discrete, reddened papules, varying in size from a pinhead to a pea. Wassermann reaction was found to be negative in the blood and spinal fluid. No tubercle bacilli were to be found in the sputum.

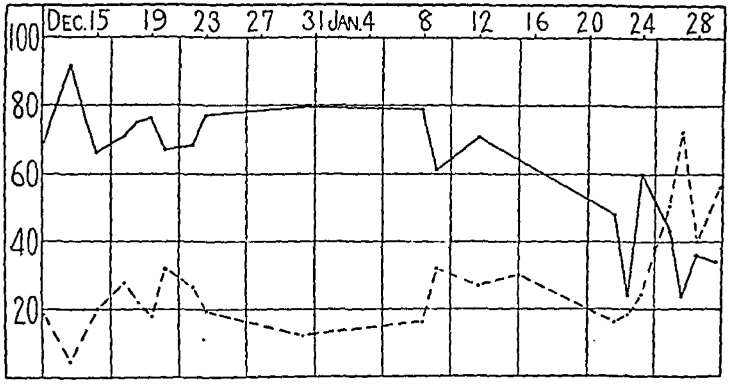

Fig. 2.—Relative numbers of normal and abnormal white cells: solid line, normal; broken line, abnormal.

Urine: Specific gravity 1.021; light cloud of albumin and a few granular casts.

First blood examination was as follows: red blood corpuscles, 5,152,000; hemoglobin, 92 per cent. (Dare); white blood corpuscles, 17,680; polymorphonuclears, 57; lymphocytes, 16; large mononuclears, 1; basophils, 26. The white cells were noted as varying greatly in size and shape.

There was no particular change in the patient for about a week except that the condition in the lungs improved; then he began to complain of a severe headache. The white blood corpuscles were 19,600, with 1 normoblast, December 13; 15,200 white cells, December 30.

December 16, gland removed showed simple, chronic inflammatory changes. The note is made that "the presence of large mononuclear cells with granular cytoplasm is suggestive of myelogenous leukemia, but the chronic inflammatory changes are the most prominent" (Dr. J. F. Cowan).

Later *leukemia of the skin* was diagnosed by Prof. William Ophüls on examination of a specimen removed.

Patient became more dazed with evident cerebral involvement and inclined to somnolence. In a blood culture taken December 26 there was a *growth of diplostreptococci in calcium carbonate infusion broth.*

Blood count, January 8: red blood corpuscles, 2,250,000; white blood corpuscles, 30,000; hemoglobin, 39 per cent.; color index, 0.86 per cent.

Differential Count (May-Grünwald-Giemsa stain):

Polymorphonuclears	58%	Basophil myelocytes	1%
Lymphocytes	11%	Eosinophil geta	2%
Large mononuclears	1%	Lymphoidocytes	1%
Eosinophils	0%	Immitationsform	1%
Basophils	0%	Normoblasts	1%
Neutrophils	23%		

New crops of reddened flattened papules occurred in different parts of the body from time to time, and small hemorrhages occurred about the eyes. The patient's condition varied from time to time, but he recovered from his stupidity and began to feel quite well day by day.

Negative blood culture, January 6. Later patient gradually became weaker, apparent thrombosis developed in some of the peripheral vessels, and patient succumbed January 31.

The following report of the morphologic blood changes was made by Dr. Thomas Addis:

"The routine differential count at the time when the patient was admitted showed the presence of certain atypical leukocytic forms. Further investigation revealed a blood picture of very unusual type.

"The red blood cells numbered 4,560,000, the white cells, 19,600. There were 64.5 per cent. of polymorphonuclear leukocytes, 27.5 per cent. of lymphocytes, 1 per cent. large mononuclears and no eosinophils. In general, therefore, no marked deviation from the usual percentage relationships. But here and there among these normal leukocytes were seen a few cells which gave evidence in their large size, large round faintly staining nucleus, and basophilic cytoplasm with sparse granules, of being in a very early stage of development. These cells were shown by means of the oxidase reaction to be of myeloid origin. They were the progenitors of the myelocytes, and showed as yet no sign of differentiation into neutrophil, eosinophil or basophil.

"Such cells of course are well known from their occurrence along with myelocytes in cases of myelogenous leukemia, and in themselves call for no remark. The point of interest lies in the fact that in this otherwise normal blood they appeared as a more or less isolated group, almost unaccompanied by their successors the myelocytes.

"A somewhat similar anomaly was found in connection with the red blood cells. A first glance at the smear gave *no indication of anything* but a very moderate grade of secondary anemia, but on further study some nucleated red cells were found. There seemed to be here again a want of some connecting link between these undeveloped cells and the great number of almost normal red blood cells.

"The further development is of considerable interest and the details are given in the chronological series of differential counts. In making these classifications the nomenclature of Pappenheim has been followed because the colored reproductions in his atlas have to some extent standardized the terms he employs. His method of using the May-Grünwald-Giemsa stain was closely followed, but quite as good results were obtained with Wright's stain. (Fig. 1.)

"The trend of development of the leukocyte changes is shown in a general way in Figure 2, which gives the relation between the number of normal white blood cells, and the number of the undeveloped leukocytes.

"As can be seen, there was no distinct change until a week before death, when the number of abnormal cells increased in number, so that toward the end there were more abnormal than normal cells. These cells were almost all promyelocytes and leukoblasts. The almost complete absence of fully developed myelocytes, which was noted as so striking in the early counts, continued to the end. On adding the percentages of all the counts made, there are only twenty-five fully formed myelocytes, as compared with 465 promyelocytes and leukoblasts. It appears as though very few of these cells had the capacity to develop into myelocytes. Their fate is probably indicated in the large percentage of unidentified degenerated cells and 'Kernschatten.'

"The red blood cells progressively diminished in number from 4,560,000 to 1,780,000 in forty-six days. At first there was a distinct secondary type of anemia, at least in so far as the color index was only 0.71, but as the anemia became more and more severe, the color index rose instead of fell until the day before death, when it was 0.92. In Figure 3, there is a graphic representation of the numbers of nucleated red blood cells found during the counting of 200 white blood cells. It will be noted that here too, as with the white cells, as the number of normal cells decreased, the number of nucleated red blood cells increased.

"During the last week the number of nucleated red cells was very large, and some enormous basic staining megaloblasts were found. The normoblasts seemed to be breaking down, and many free nuclei were thus liberated. In consequence it became difficult in many cases to distinguish between small lymphocytes and nuclei of normoblasts to which a rim of polychromatophilic cytoplasm still adhered. In spite of these large numbers of early forms of red blood cells, the non-nucleated red blood cells showed none of the degenerative and regenerative changes which are usually found when normoblasts and more especially megaloblasts are present in the blood.

"To sum up, it may be said that the blood presented the remarkable combination of cells typical of an acute myeloid leukemia (lymphoidocytes, leukoblasts and promyelocytes) and of an acute pernicious anemia (gigantoblasts, megaloblasts and normoblasts) together with a large proportion of normal well-formed fully developed cells."

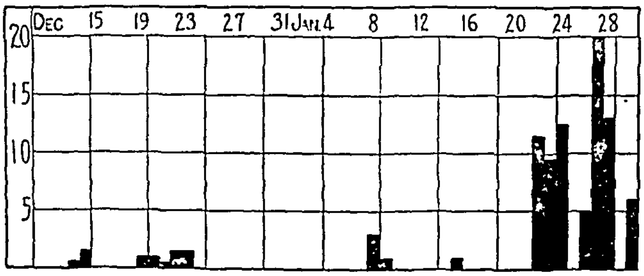

Fig. 3.—Increase in number of nucleated red cells as fall in number of normal cells takes place.

The accompanying table shows the differential counts, red and white cell counts and hemoglobin estimations from the time the patient came under observation to the day of his death.

Necropsy.—The necropsy, of which the following is a record, was performed by Prof. William Ophüls, Jan. 31, 1914.

On opening skull, some dark brown blood escapes from left side. Skull cap is normal.

Strongly built extremely emaciated man of about 60 years. Marked arcus senilis. Skin and visible mucous membranes extremely pale. Teeth fairly well preserved and poorly kept. Marked enlargement of deep cervical supraclavicular and axillary lymph glands on left side. Marked enlargement of glands in both inguinal regions. In skin over chest, both upper arms, belly, thighs and on back are large number of white projecting nodules from just visible to 3 mm. in diameter. Majority are surrounded by hemorrhagic zones. Skin over back of both hands markedly atrophied and full of hemorrhages. Irregular hemorrhagic discoloration of skin on dorsum of right foot. Left foot deeply cyanosed. Tissues shriveled and dry. No edema. Old irregular scars with pigmented margins, largest one 8 by 5 cm. in diameter. Very marked atrophy of subcutaneous fat and muscle. Peritoneum pale, moist. Liver projects 2 fingerbreadths in right mammary line. Stomach and transverse colon in normal position. Appendix back of cecum, which is distended markedly with feces. Marked atrophy of omentum. No free fluid in peritoneum. Numerous small hemorrhages in periosteum of ribs. Diaphragm fifth on left, right-fourth ribs.

Strong adhesions between anterior part of left lung and sternum. In ribs there is very little bone marrow. On pressure there escapes a thin very slightly turbid fluid. Bone marrow of sternum is light grayish red. In some places are large hemorrhages. Fairly easily broken old adhesions very nearly obliterating pleural left cavity. Similar adhesions on right base. Easily broken adhesions on right apex. Few small hemorrhages in pericardium. Extensive, easily broken old fibrous adhesions about spleen. Capsule is irregular, thickened and deeply pigmented, 12.5 by 9.5 by 5 cm. Cut surface of spleen shows brownish-red color with purple spots beneath capsule. Pulp is quite soft.

Heart is of normal size. Large milk spot over right ventricle. Large postmortem clots in pulmonary artery. Wall of right ventricle very thin, dark brown.

Along closing line of posterior part of large, and of small flap of mitral, also on closing line of two of the aortic cusps, are small grayish apparently quite recent thrombotic deposits. Deposits on aortic valves are slightly thicker. Base of aorta and coronary arteries normal. Heart muscle on left side, dark brown and flabby.

Old scars at base of mesentery of sigmoid flexure. Large amount of thin yellow fecal material in sigmoid flexure and rectum. Small amount of light clear urine in bladder.

Diagnosis: Leukemia. Endocarditis, acute. Pachymeningitis, hemorrhagic. Bronchitis, acute. Bronchopneumonia.

Smears: Aortic valve: Many reds, many myelocytes, no bacteria. Mitral valve: Many reds, many myelocytes, *moderate number of diplococci.*

Marrow: Many large neutrophilic myeloblasts, few neutrophilic leukocytes, few basophilic myelocytes, very few eosinophilic myelocytes, few nucleated reds, few large vacuolated cells containing fragments of cells and of nuclei, also some pigment, *few groups of diplococci partly free, partly in phagocytes,* few normoblasts.

REPORT ON THE MORPHOLOGIC BLOOD CHANGES IN CASE 3

	December										January

Spleen: Many neutrophilic myeloblasts, few neutrophilic and eosinophilic leukocytes, many small and large lymphocytic cells, no bacteria found.

Microscopic Examination.—Bone: Very cellular marrow rich in myelocytes, periosteum shows marked infiltration with myelocytes.

Spleen: Marked hematogenous pigmentation. Malpighian bodies small; pulp crowded with large myelocytes.

Lymph gland: Marked quite diffuse infiltration with myelocytes.

Heart valve: Shows fibrous cellular thickening on one side covered with thrombus. Thrombus is very dense, free from cells.

Section of skin shows accumulation of myelocytes about blood vessels in cutis.

Abdominal aorta: Large atheromatous ulcer.

Lung: Hyperemic, few pigmented scars. Blood in blood vessels rich in myelocytes.

Kidney shows few small arteriosclerotic scars, many small areas of myelocytic infiltration.

Liver shows moderate filling of capillaries with myelocytes, some also in periportal connective tissue.

Lung shows bronchitis and beginning bronchopneumonia.

Radial artery shows slight arteriosclerosis.

Sections of marrow show large necrotic areas apparently due to thrombotic masses in vessels. Much fibrin between necrotic cells; large hemorrhages at edge of necrosis; also quite advanced organization in some places. No bacteria found in necrotic areas. The adjoining living marrow is crowded with a moderate number of mitoses; myeloblasts; shows few red cells and very few nucleated reds. Very few eosinophilic myelocytes. Scattered throughout the marrow one finds a considerable number of large phagocytic cells which contain fragments of degenerated cells, frequently pigment and finely granular detritus. *In some of these cells groups of diplococci as described in smears. There are also few scattered diplococci free in the marrow.* One of the sections of marrow is somewhat different from the rest (probably section of vertebra, whereas others are from ribs and sternum). In this piece there are no necroses. The proliferation of myeloblasts is still more marked and occurs in the form of small badly defined tumorlike nodules which measure about 2 mm. in diameter. No bacteria found in these slides in spite of continued search with mechanical stage.

COMMENT

We have, then in the foregoing cases one of the acute lymphatic type with mediastinal tumor, a practically normal blood count when first seen and then with the clinical picture of an acute infection, rapidly increasing lymphocytosis, hemorrhage and death, another with similar mediastinal tumor but with a more prolonged course, but so evidently an infection as to be confused with pulmonary tuberculosis; and a third with slow development, typical skin and other reaction and with evidence of the involvement of the whole bone marrow, including the red blood cell forming portions (Pilcher[56]). The bacteriologic studies made of the last two cases were not at all conclusive, but were suggestive. In Case 3 streptococci were found in the blood thirty-three days before death. The early invasion of the bone marrow seems proved by the study of the blood given above, the changes in the white blood corpuscles and the appearance of megaloblasts and normoblasts, together with the progressive anemia. The definite relationship of bone-marrow infection to pernicious and other anemias and to the leukemias is certainly favored by a careful study of this patient. In infections it seems at times as if one part of the bone marrow responds, the red cell forming (Gorjaew[42]), and then in another white cell deviations occur; but here toward the end all parts of the bone marrow seem involved. This is, of course, accompanied by more or less change in the spleen, lymphatic tissues, etc. It is true that while streptococci were found in the marrow after death, they were not so placed as to be clearly present in the lesions characteristic of leukemia. This may be a secondary infection with streptococci, but clinically the picture of a progressive bone marrow infection with primary involvement of the white blood cell forming portions is difficult to lay aside. In Case 2 the streptococci are more evidently terminal invaders. The skin lesions in Case 3, with their surrounding hemorrhagic areas, certainly could readily be interpreted as metastatic (Hitschmann and Lehndorff,[57] Arndt[35]) processes such as we commonly see in streptococcic infections even of low virulence, and they speak for the infectious origin of the disease.

The well-known wide range of activity shown by the streptococcus, and its tendency to obtain and retain a foothold for long periods of years within the body in the endocardium, tonsils, bowel, about the teeth and elsewhere would indicate the strong probability that the bone marrow is often likewise infected and that streptococci may retain a hold there and so induce the more chronic types of lesions associated with leukemia. In California, low-grade diplostreptococci infections are common, such as the characteristically mild rheumatic fever erythema nodosum, probably erythema multiforme, bacterial endocarditis, at least some cases of hyperthyroidism, tonsillitis, intestinal lesions, etc. These, or tuberculosis, or both, may explain the fact that the lymphocyte count, as has been shown by Mehrtens,[58] is apt to be high, at least in San Francisco.

These points with others lend color to the belief that the actual presence of streptococci in the bone marrow has a definite etiologic part to play in the development of the leukemic picture observed. Only by further bacteriologic and perhaps protozoologic studies of the blood, bone marrow, spleen and lymph glands of such patients, and by animal inoculation from the tissues involved, including bone marrow trephined from living bone, can we clarify this problem.[59] If we can force the leukemias into the diseases of known origin we have gone a long way toward the solution of a reasonable and effective therapy. Remedies damaging the bone marrow, such as benzol (benzene, C_6H_6) and chloroform are now in common use, but they are dangerous and usually fail. We must not let the fact of chronicity in many cases divert our attention from the possibility that there is an active, even though mild, infection going on. Unfortunately there is at present not sufficient evidence accumulated to give assurance as to the real cause of leukemia, but we feel justified in the following conclusions:

CONCLUSIONS

1. The evidence thus far available points strongly to infection as the cause of the leukemias. It is probable that organisms usually of low virulence but of various kinds, perhaps working on a soil prepared by

[59] Hansemann (Berl. klin. Wchnschr., 1914, li, 9) has asked that all such information be reported to him in order that he may assemble all available information pointing to infection as the cause of leukemia.

previous infections, can, when they secure a foothold in the bone marrow, spleen or lymphatic glands, bring about the leukemic reaction alone or combined with disturbance of the red blood cell forming mechanism.

2. Streptococci have been more frequently reported than other organisms in the blood and tissues of leukemic patients.
3. The attempt to classify rigidly the leukemias and pseudoleukemias on purely morphologic grounds is futile.
4. A long series of bacteriologic studies, including blood cultures and bone marrow inoculations from living patients, will be required to settle the relationship of infection to the leukemias as well as the anemias.
5. Foci of infection should be sought, and treatment directed against them. Only with the establishment of the cause can we hope for a sound therapeusis of this condition.

ABSTRACT OF DISCUSSION

Dr. Carl R. Krone, Oakland, Calif.: I must agree to Dr. Wilbur's conclusion that leukemia is an infection, in particular the result of infection of the bone marrow. My findings, important by themselves in other respects, show that twenty-four hours after administration of chloroform in a case of tuberculosis of the lungs followed a period of hematopoietic activity expressed by a gradual increase of leukocytes and a likewise gradual decrease of erythrocytes. This activity was not due directly to the 20 c.c. of chloroform inhaled during one hour at each treatment, because the result, a maximum of 19,000 leukocytes and a minimum of 1,520,000 erythrocytes, was achieved only at the end of fifteen days, when the chloroform had long been eliminated. The chloroform, however, I claim, may have dissolved the lipoid matter surrounding the tubercles; also probably extracted at least in part the waxy substances of the capsules of individual bacilli, rendering the latter less viable or more vulnerable, and carried numbers of them away in the blood stream. The leukocytogenetic function was stimulated by this sudden invasion of less virulent bacilli and we witness a powerful influence on the entire hematopoietic system. This is the fact which connects my findings with Dr. Wilbur's conclusion that leukemia is an infection. In my case the blood picture, abnormal after fifteen days, approaches the normal in thirty days more. There are no myelocytes or other abnormal white cells, indicating by their absence that the hematopoietic system has not become injured by infection of the bone marrow. However, we may not exclude a possible infection and injury of that system and consequently a possible leukemia, especially if the *causa morbi* be not *Bacillus tuberculosis* but diplostreptococcus. Dr. Wilbur sees the case at the end of the story, when the *causa morbi* cannot any more be eliminated. I see the same case at its beginning, when the hematopoietic system is still intact and responds to normal stimulation of its defensive elements against an apparently less virulent invasion. I may add that clinically my tuberculous patient is doing well under the treatment with chloroform inhalation.

Dr. Max Einhorn, New York: The question whether leukemias are infectious is very important, and the mass of experience would tend to favor such a view. In acute leukemia we have more evidence as to the infectious character of the disease. I will only mention one case in my own experience, in which sickness began with disease of the throat, an acute condition that first appeared to be an acute tonsillitis. The patient was treated for a week or so and then came to the hospital and was under my observation. In a few days he developed more throat symptoms, swelling of the tongue and larynx, and soon we were able to make a diagnosis of acute leukemia. The lymphocytes were greatly increased. I think they amounted to 92 per cent. of the white blood corpuscles. He had a very high degree of leukemia, the white blood corpuscles being one to four or five of the reds. He died in four or five weeks, the symptoms being those of an acute type of irregular fever with swellings and hemorrhages. That is the way the acute leukemias do; the patients die in a month or two. Dr. Sunderman of New York has made observations in which the acute leukemia could apparently be traced to an infection. In my own case no blood cultures were made and no definite bacteriologic proofs were obtained, but clinically it was undoubtedly an infection. In one case a streptococcus was found. Possibly that was not the real cause of it, but there must be something that leads to the infection. At any rate, these cases are of great importance and I think we should all try to furnish material for study and not rely on necropsies in the study of the leukemias. We should be able to recognize the disease before necropsy.

Dr. J. A. Lichty, Pittsburgh: I think we all agree that it would be very fortunate if we could find the cause for the primary anemias in infection. Dr. Wilbur's paper carries us one step further in this direction when we find infections such as he has described. Yet there are many questions which come up, especially as to whether the micro-organisms which he found in his case were after all the etiologic factor. In many of these primary anemias, and especially in pernicious anemia, we find an elevation of temperature toward the termination of the disease. We can hardly think of anything else but that there is an infection, probably a terminal infection. Probably the vitality of the organism is such that micro-organisms which are not harmful ordinarily for the normal body become virulent and pervade the various tissues. I regret very much that Dr. Rosenow is not here to discuss this paper, because he has done so much work along the line of the subinfections. In pernicious anemia particularly we see the terminal elevation of temperature. In a fatal case of pernicious anemia at the Mercy Hospital, Pittsburgh, colon bacilli were recovered from the bone marrow, which was very interesting but hardly conclusive. Such work as Dr. Wilbur's will have to be pursued until we prove or disprove the infectious nature of these diseases.

Dr. R. L. Wilbur, San Francisco: I have no idea of claiming that we have proved that the diplostreptococci are the cause of leukemia. But we have found the diplostreptococci, and we have much proof that leukemia is infectious. It is important to make studies of the bone marrow in these cases, particularly from living patients, which will probably advance our knowledge of this disease much more rapidly than in the past. Specimens for such study may be readily removed under general or local anesthesia. It is important to take care of foci of infection. As to the care of the tonsil in leukemia, that is a question. Are we to take out the tonsils in leukemia? There is the possibility of a lighting up of the process and the death of the patient. If the affection of the tonsils seems to be responsible for the leukemia, we should take them out.

Defects in Schoolchildren.—The *Bulletin of the Chicago School of Sanitary Instruction* says regarding medical school inspection work that it is a service rendered by the department of health for which the taxpayers pay, but unless the parents do their share by having defects attended to after their discovery by the inspectors the money expended is wasted. The department's figures regarding this matter are interesting. In 1914 there were 75,476 examinations made. 45,176 children were found defective and 35,425 were advised to seek treatment. In each of these instances the parents were informed by a note of the nature of the ailment and treatment was suggested, but only 9,244, or 40 per cent., acted on this advice. In detail the figures were as follows: Of 4,054 cases of adenoids, 737, or about 18 per cent., were treated; diseased tonsils, 5,754 cases, of which 223, or a little over 4 per cent., were treated; discharging ears, 1,254 cases, of which 118, or a little over 10 per cent., were treated; defective vision, 9,364 cases, of which corrections were secured in 1,826, or a little over 12 per cent.; diseased eyes, 7,449 cases, of which 138 were treated, or a little less than 2 per cent.

to 103 in twenty-seven cases. After operation, the temperature either remained normal from the day of operation or returned to normal in seventeen cases; ten were normal the first day after operation, making twenty-seven cases; five returned to normal on the second day after operation, making thirty-two; three returned to normal on the third day, making thirty-five; one returned to normal on the fourth day, making thirty-six; two, fifth day following operation, making thirty-eight, while only two persisted with elevated temperature for seven days. Twenty-three had a leukocytosis before operation of over 9,000, some as high as 30,000, showing another evidence of probable infection. As to the cause, twenty-four stated that abortion came on spontaneously, and sixteen acknowledged that they had brought it on criminally. Of late it has been our practice to test the mothers for syphilis in case of an unexplained abortion. In four recent cases, all gave a negative Wassermann on examination. I present these statistics, hurriedly gathered together, to show that patients can be well treated by clearing out the uterus promptly, although at the same time I am sure Dr. Montgomery can in general practice show that many patients can empty the uterus spontaneously and are better untampered with. I wish to point out, however, that at present I cannot see the reason for not emptying the uterus in abortion.

Dr. John Osborn Polak, Brooklyn: Before this section and before the American Gynecological Society we have called attention for several years to the treatment of infected cases by the so-called palliative methods (so-called judicious neglect plan) versus operative procedure, and our results have been so exceptionally good that we have rather felt that the profession should share with us in the little knowledge that we have gained by the study of this procedure.

We divide abortions into the infected and the noninfected cases. I do not believe that any of us feel that in a noninfected case the uterus cannot be entered with safety and if the evacuation is complete and clear, perhaps the convalescence of that patient will be expedited; but I do know that the infected case which has protected itself, as each infected case does protect itself, by a leukocytic wall, and if a placenta is present and thrombi are formed in the vessels in the placenta site, that the infection is spread and the patient's condition is jeopardized by the routine procedure of curettage.

The question of interference in abortion is this: Is there hemorrhage or is there not hemorrhage? If there is no hemorrhage, our experience has been, even when the temperature is 104 or 105, that those patients, if placed in the Fowler position, an ice pack put over the abdomen and elimination maintained with saline solution and intestinal rest, with no cathartics and no food, show—inside of twenty-four to seventy-two hours—great improvement; the products will separate, for they have been starved off by the formation of the round-cell deposits, and the product of conception will be delivered completely, if left alone, in the large majority of cases. If it is not delivered spontaneously, it is found with the uterus contracted and this large mass lying in the dilated lower segment of the uterus. We have, for instance, reported twenty consecutive infected cases before the International Congress, with the complete contents of conception left *in situ*; every one of those patients made a complete recovery, the uterus expelling its contents spontaneously, and we believe just in proportion as these cases are interfered with, so is the morbidity increased. In a hundred consecutive cases, sixty-three had been curetted one or more times, and all of these showed exudates. On the other hand, in 200 consecutive cases admittedly infected, without interference, we found that in this series of cases our morbidity as to exudates and as to mortality was decreased. It is a pleasure to hear Dr. Montgomery, whose word covers such weight, protest against this active interference in abortion.

Dr. C. Lester Hall, Kansas City, Mo.: We all feel keenly the outrage that has been committed by the profession on the pregnant woman in the way of producing abortion. It is now many years since I first heard a man, or several men of high standing, in the discussion of this subject, flatly acknowledge a willingness to produce abortion in the maiden who had been unfortunately caught. My protest on that occasion, whether it had any lasting effects or not, was so emphatic that it has been my good fortune not to hear these men repeat this statement. The outrage is so monstrous that we cannot accentuate it too strongly. I feel that it is not done now as it once was done. I believe the profession is rising above this nefarious practice. In regard to the treatment of abortions, I think it depends very much on circumstances. I believe it would be justifiable in almost any case, if the obstetrician were sufficiently clean, to empty the uterus with a blunt instrument; to swab out the uterus once, and never again. It is the continual meddling that brings dire results, and even with all our care it is liable to produce septic conditions.

I know the value of the protective wall that nature has thrown out, and over and over again it has been my fortune, and I believe with good results, to stay the hand of the energetic, aspiring young obstetrician who wanted continually to meddle with these cases. We know the deleterious effect of uterine douching. In regard to giving these patients potassium iodid, that Dr. Montgomery refers to, to make a woman carry a baby to term, I would object to the giving of the potash. I think we might give iodin itself with safety, but in all these cases we are apt to have more or less kidney trouble, and I believe in giving potassium iodid we load up the system with this potash which is toxic and detrimental. I protest that in women with albuminuric conditions we should avoid the use of potassium iodid or other potash salts.

In regard to retrodisplacements of the uterus of the pregnant woman, it is a great misfortune if we cannot institute some measure whereby we can make this woman carry her child to term and prevent the recurrence of the retrodisplacements. This is the *only* nonsurgical way we can correct these displacements. This I have often done, and by the postural treatment after delivery recurrence of the retrodisplacement has been prevented. This will happen in 99 per cent. of all cases in which the retrodisplacement has existed before pregnancy.

The subject is so important, and coming from Dr. Montgomery, is so effective that I am sure if any young man here has been imprudent in the use of instruments after abortions, the doctor's paper will have a lasting good effect, and it will do us *all* a great deal of good.

Dr. S. M. D. Clark, New Orleans: It seems that we are about to agree on some standard method in handling abortions. In noninfected cases I believe with Dr. Montgomery the sanest plan is to empty the uterus with as little traumatism as possible and then leave an iodin wick for twenty four hours. The infected abortions are the ones on which there are still divergent opinions. It took a goodly experience before I could break away from the old plan of emptying the uterus in these cases. After all, the pathology should guide us, and when this is thoroughly understood, the locally inactive plan is the method that best complies with these laws. When called in consultation, how often have each of us found the physician giving daily intrauterine douches; he generally curets and if the temperature materially rises, feeling that there is still something remaining, he again curets. The pressure of the anxious family forces him into some local activity; he feels that he must be doing something, so he goes ahead douching and curetting. This daily mauling is repeated, not so much for the patient, but for the family. Where the infection is already beyond the endometrium, nothing could be more unreasonable than to expect relief by superficially fussing around in the interior of the uterus. Let such cases alone, adopt the locally inactive plan, furnish an abundance of fluids and keep the patients well nourished. The infection in practically every case will localize; an immunity will be established; the patient will autogenously vaccinate herself and the exudate either resolve or suppurate.

The importance of the lower segment of the uterus in these infected abortion cases has not been given due consideration. In many of our cases the upper segment is never involved, but rather the infection has struck directly out toward the parametrium through the richly supplied lymphatic circulation of the cervix. This is the type in which the true pelvic connective tissue abscess is found, which when drained is immediately cured. Could anything be more unreasonable than to curet in such cases? I think a point to be driven home is the extreme importance of exercising the most rigid asepsis when making vaginal examinations in diagnosing cases of abortion. The vaginal canal should be explored with the same aseptic regard as one would invade a knee joint or the abdominal cavity.

DR. H. G. WETHERILL, Denver: In the treatment of these cases it is important to determine whether one is dealing with a spontaneous abortion or a mechanically induced abortion. Infections of the genital tract are commonly retrograde infections if the abortion is mechanically induced, or if there has been gynecologic tinkering. If, on the other hand, it is an incomplete abortion, not of the mechanical type, then we certainly are justified in picking out with the placental forceps any retained portion of the product of conception which might otherwise give rise to sapremia. With this exception, I agree wholly with the principles of treatment set forth by Dr. Montgomery and I am heartily in accord with him in his strictures on the abuse of the uterine curet in such cases. So careful should we be in handling infected cases that a tenaculum or volsellum forceps should not be used to draw down and fix the cervix, as the small punctures made by the teeth of the instrument are sufficient to reinoculate a patient from the vaginal and cervical secretion.

For many years I have treated infections following abortions with alcohol after the method of Caruso. A double drainage tube of large caliber is inverted on itself, so that the solution cannot follow the tube. This tube is introduced to the fundus with strict antiseptic precautions and the alcohol which is used through it flushes the genital tract from the fundus outward with a nonpoisonous, antiseptic solution. Occasionally a solution of permanganate of potash or a diluted solution of iodin is substituted for the alcohol. In the treatment of such cases it is very easy to do too much and almost impossible to do too little. The majority of the patients will recover if let alone.

DR. E. E. MONTGOMERY, Philadelphia: I must confess that if called to a woman who had an abortion or was aborting, in whom a portion of the embryo had escaped, whom I had reason to feel was not an infected case, and in making a careful aseptic examination discovered a portion of the placenta projecting, I should be tempted at once to evacuate the uterus; but in cases such as one of the gentlemen mentioned in which the mass is situated within the body of the organ, the cervix, possibly, more or less contracted, the result of leaving the case to nature, treating it carefully, aseptically, will be attended with much less danger to the patient than would be the mechanical dilatation of the uterus and the removal of the structures within. I believe, also, in those cases of which Dr. Wetherill has spoken, in which a portion of the placenta remains and it is evident that sapremia exists, it is better to leave the condition undisturbed and trust nature to evacuate it rather than use mechanical measures.

Railway Accidents.—According to *Accident Bulletin 55* of the Interstate Commerce Commission, for the first quarter of 1915 the number of persons killed in train accidents on steam railways was 65, and the number of persons injured was 1,972. The total number of persons killed in all classes of accidents incident to railways was 1,650, and the number injured was 35,429. This includes 68 persons killed and 21,582 injured in so-called "industrial accidents," which are defined as accidents not connected with train operation, but occurring to railway employees, other than trainmen, on railway premises.

PLACENTAL BACTEREMIA*

J. MORRIS SLEMONS, M.D.
Professor of Obstetrics and Gynecology, Yale Medical School
NEW HAVEN, CONN.

When the fetus is stillborn or the infant dies within a few days after its birth, frequently we are unable to determine the cause of death. This fact has been emphasized in the statistical analyses recently published from two American institutions. At the Sloane Hospital for Women[1] among 10,000 consecutive confinements there were 429 stillbirths and 291 infants which died within two weeks after they were born. Reviewing an equal number of confinements at the Johns Hopkins Hospital, J. Whitridge Williams[2] found 705 cases of stillbirth and early infant death. The fetal mortality in these clinics, it would seem, is practically identical. And in both series of statistics it is instructive to find that, although careful clinical observations and postmortem examinations were made, the cause of death was not ascertained in roundly 20 per cent. of the fatal cases.

Some time ago my attention was called to a cause of fetal death not widely appreciated and one which is left out of account in the reports just quoted. Whenever membranes rupture prematurely and the labor is prolonged, especially if repeated vaginal examinations are made, bacterial invasion of the placenta—placental bacteremia—may occur. This complication constitutes a serious danger for the fetus. Its relative importance as a factor in infant mortality is difficult to estimate but its practical significance is certain.

With reference to this question I have studied five hundred consecutive confinements under my care while connected with the University of California Hospital. Including infants over 40 cm. long the mortality was 5.4 per cent. (27 cases). The infant was stillborn in 21 cases; it died on the second day in 3, on the fourth in 2, and on the ninth in 1 case. A necropsy was performed in every instance. The causes of death were as follows:

	Cases	Per Cent.
Syphilis	7	26
Birth injury	6	22
Premature separation of placenta	4	15
Placental bacteremia	3	11
Congenital heart lesion	2	7
Enlarged thymus	1	3
Toxemia pregnancy	1	3
Undetermined	3	11

A number of well-known factors combine to explain why the fetal mortality is higher in case labor is prolonged. With 62 of my patients labor lasted longer than twenty-four hours and in this group 8 fetal deaths occurred (13 per cent.). Three of the deaths were due to placental bacteremia. The mothers of these infants were not seriously ill and at the end of two weeks were discharged from the hospital in good health. Such results, it will be made clear, are not always to be expected. But before considering the experience of other observers I may summarize the histories of my cases, giving only the facts pertinent to the problem under discussion.

CASE 1.—Primipara; aged 20; generally contracted rachitic pelvis with diagonal conjugate measuring 11 cm. Presentation right occipitoposterior. Duration of labor twenty-eight hours: membranes ruptured six hours before delivery by midforceps. Several vaginal examinations were made but the number was not recorded. Temperature during labor, 37.8 C. (100 F.); pulse, 70. Highest puerperal temperature, 37 C. (98.6 F.); pulse, 98.

* Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

[1] Holt, L. Emmett, and Babbitt, Ellen C.: Institutional Mortality of the Newborn, THE JOURNAL A. M. A., Jan. 23, 1915, p. 287.

[2] Williams, J. Whitridge: Limitations and Possibilities of Prenatal Care, THE JOURNAL A. M. A., Jan. 9, 1915, p. 95.

The child, 48 cm. long, weighed 3,080 gm. It was easily resuscitated. Death occurred on the third day. At necropsy the umbilical stump was dry and clean. The abdomen contained 250 c.c. of seropurulent fluid which showed streptococci in cover slips. There were subpleural ecchymoses over the left lung, but no intracranial hemorrhage and no meningitis. The brain was normal.

Sections of the placenta and umbilical cord stained with hematoxylin and eosin were normal. Sections of the placenta stained by the Gram-Weigert method showed a few streptococci just beneath the amnion in the neighborhood of the fetal blood vessels. Bacteria were not demonstrated in the cord.

Case 2.—Primipara; aged 23; normal pelvis. Presentation left occipito-anterior. Labor began with rupture of the membranes and after forty-five hours terminated normally. Six vaginal examinations were made. Temperature during labor, 38 C.; pulse, 108. Highest puerperal temperature was 38.2 C.; pulse, 110.

The child, 52 cm. long, weighed 3,540 gm. Resuscitation was difficult. Death occurred at the end of forty-eight hours. Shortly after its birth the infant bled from the mouth, and later patches of purpura appeared over the head, buttocks, scrotum and right knee. At necropsy a small blood clot was found on the parietal peritoneum adjacent to the umbilical vessels and another beneath the liver. The peritoneal cavity contained about 10 c.c. of uncoagulated blood but none was found in the intestines. There was no blood in the pleural cavity. Several hemorrhages the size of a pinhead were found at the base of each lung.

Sections of the placenta stained with hematoxylin and eosin were normal but the umbilical cord was infiltrated with leukocytes, most pronouncedly in the neighborhood of the vein. Stained by the Gram-Weigert method streptococci were demonstrated in the amniotic and chorionic connective tissue near the fetal surface of the placenta. Streptococci were also present in the cord.

Case 3.—Primipara; aged 38; normal pelvis. Presentation left occipito-anterior. Membranes ruptured when the cervix was dilated 5 cm., twenty-four hours before delivery was effected by midforceps. Temperature during labor, 37.8 C.; pulse, 106. Highest puerperal temperature, 38.5 C. (101.3 F.); pulse, 115.

The child, 50 cm. long, weighed 2,980 gm. For an hour before delivery the fetal heart sounds were not heard. The necropsy findings were negative except for a small cerebral hemorrhage beneath the left occipital lobe.

Sections of the placenta showed partial thrombosis of many of the vessels which pass over the fetal surface of the placenta. Large numbers of bacteria were demonstrated in the amnion covering the placenta and in the underlying chorionic connective tissue. Streptococci and also a short, stout bacillus, resembling the gas bacillus, were present. A few streptococci were found in the intervillous spaces but the chorionic villi were normal. A typical mixed thrombus almost completely blocked the umbilical vein. It contained streptococci as did also the wall of the vein and the surrounding Whartonian jelly. The walls of the umbilical arteries were slightly infiltrated with leukocytes but no bacteria were demonstrated there.

In all these cases organisms were demonstrated in the subamniotic connective tissue where they came in contact with the large fetal blood vessels which cross the surface of the placenta. In one instance it was possible to demonstrate bacteria in the act of penetrating the walls of these vessels. It is also noteworthy that in every case the epithelium which covers the villi was intact, the capillaries within the villi were of normal appearance, and no bacteria were found either on the surface or in the interior of the villi. Evidently the infection did not proceed from the maternal circulation and did not pass through the walls of the villi. The bacteria entered the placenta by way of the amniotic membrane. Most frequently, as in these cases, placental bacteremia depends on the infection of the amniotic fluid; and generally the latter complication occurs because the membranes rupture prematurely, labor is prolonged, and repeated vaginal examinations are made.

From a knowledge of the anatomy of pregnancy it is obvious that, at least theoretically, the infection of the amniotic fluid is possible by three routes; (1) organisms may pass from the maternal circulation across the decidua, the chorion, and the amnion; (2) they may travel from the peritoneal cavity down the fallopian tubes, or (3) they may ascend from the vagina through the cervical canal. In a series of animal experiments the progress of an infection along each of these paths has been demonstrated by Hellendall,[3] but only the third has a broad, practical significance in human pathology. It has not been established that the other routes ever play a rôle except under conditions that have been imposed experimentally. And yet, it is possible in human beings that hematogenous infection of the amniotic fluid may be the result of a maternal septicemia; and also that in case of acute inflammation of the appendix during pregnancy the responsible organisms may find their way down one of the fallopian tubes. At all events, in the cases I have observed, neither septicemia, appendicitis, nor peritonitis existed; on the other hand, ideal conditions prevailed for infection of the amniotic fluid by the vaginal route.

When the membranes have ruptured, an increased liability to infection is apparent; and some have taught that bacterial invasion of the amniotic cavity occurred while the membranes were intact. The evidence favoring the latter possibility, however, is not conclusive, as it has never been confirmed by bacteriologic examination. In the cases recorded by Lehmann, Carpentier, Brieglet, Lendanthal[4] and others, the foul smelling decomposed amniotic fluid which escaped when the membranes ruptured may have been due, as these observers suggest, to bacterial putrefaction; but in the absence of cultures it remains to be proved that the unruptured membranes are not an effectual barrier against the passage of bacteria from the vagina to the amniotic cavity.

Although under suitable conditions a great variety of pathologic bacteria may invade the amniotic fluid, the streptococcus has been the predominating organism found in cases of placental bacteremia. Frequently colon bacilli are associated with streptococci. In the case of tympanitis uteri during labor the colon bacillus was regarded as the exclusive etiologic factor until, in one instance, Krönig[5] demonstrated an obligatory anaerobic bacillus. Warnekros[6] has isolated the gas bacillus from blood cultures in several cases of placental bacteremia. And in one of my cases placental sections showed a short, stout bacillus corresponding morphologically with the *Bacillus aerogenes capsulatus* though its identity was not established by means of cultures.

[6] Warnekros: Arch. f. Gynäk., 1913, c, 173.

From the nature of the lesion in placental bacteremia, an infection within the uterus, generally limited to the amnion and the chorion and often most pronounced in the neighborhood of the large vessels passing over the fetal surface of the placenta, the associated clinical problem pertains both to the mother and to the child. Thus far, its maternal aspects have aroused the greatest interest. And this interest has been stimulated chiefly by a desire to determine whether a true uterine infection was responsible for intrapartum fever.

Glockner[7] thought the existence of an infection was unnecessary to explain intrapartum fever. Frequently in these cases the temperature becomes normal immediately after delivery, or presents only a slight temporary rise during the puerperium. Consequently, Glockner assumed pathogenic bacteria were not present, and ascribed the intrapartum symptoms to prolonged and violent uterine contractions. Winter[8] favored this view but also admitted that bacteria might be indirectly concerned. According to Winter's hypothesis the symptoms were occasionally explained by the absorption of toxins from a decomposing ovum. On the other hand, Hausen, Krönig, and Hellendall declared that intrapartum fever, like puerperal fever, depended on a bacterial invasion of the maternal tissues.

It occurred to Warnekros that this difference of opinion could be settled if cultures were made from the mother's blood in case her temperature during labor rose above 38.5 C. The procedure was adopted in 25 cases; the cultures from 18 cases were positive, from 7, negative. In 9 instances streptococci were isolated, in 3 staphylococci, and in the other positive cases colon bacilli, pseudodiphtheria bacilli, or anaerobic gas-producing bacilli; not infrequently more than one type of organism was isolated. Whenever a positive culture was obtained during labor, another was made on the day following delivery. The puerperal cultures were negative except in one instance—the case of a patient who died of a streptococcus septicemia on the third day postpartum.

In approximately 70 per cent. of the cases of intrapartum fever it was clear that a genuine, if temporary, infection of the mother existed. The cause of the fever in the other cases was uncertain. Consequently, the scope of the investigation was broadened, and sections of the placenta were stained for bacteria. In every instance, even though the blood cultures had been negative, organisms were found in the placenta. And, therefore, Warnekros concluded that intrapartum fever, unless attributable to some accidental cause, as tuberculosis, was due to an infection of the mother, often mild and temporary, and that a placental bacteremia was always demonstrable.

The character of the puerperium which will follow a febrile labor may best be predicted from the result of blood cultures taken the day after delivery. Generally, these are negative and a good prognosis is assured. On the other hand, positive cultures indicate the existence of a puerperal infection. Blood cultures at the time of labor have no prognostic value. Similarly, as a prognostic sign the degree of fever at the time of labor is unreliable, for Winckel[5] observed several patients who experienced a puerperal convalescence free from fever in spite of an intrapartum temperature above 39 C. (102.2 F.).

The puerperal morbidity in cases of intrapartum fever, an average based on the report of 944 cases by five observers, would seem to be about 63 per cent., the puerperal mortality 6.2 per cent.

RESULTS FOR THE MOTHER FOLLOWING INTRAPARTUM FEVER

In case of intrapartum fever the outlook is much more serious for the infant than for the mother. The fetal mortality encountered by Ihm was 18 per cent., by Hellendall 19 per cent., by Winter 35 per cent., and by Kronig 61 per cent. These statistics include cases of toxemia of pregnancy, of placenta praevia, of pelvic contraction, and of malposition of the fetus. Therefore, the death of the fetus may have been due to one of several causes, and, lacking the requisite examination, it is impossible to determine to what extent the infection of the placenta was concerned.

At present I am content to emphasize the fact that intrapartum infection must be regarded as one cause of fetal death, and also to demonstrate that the umbilical vessels may be the path of the infection. Heretofore, it has been assumed that antepartum infection of the fetus depended on its swallowing or aspirating the infected amniotic fluid. At most, Krönig has said, blood-borne infections to the fetus are limited to cases in which the mother is suffering from septicemia, as in typhoid fever, pneumonia, tuberculosis or cholera. But another possibility must be reckoned with, namely this: If the amniotic fluid is infected, the bacteria may cross the amnion and invade the placental vessels which carry blood to the fetus.

In one instance I have noted an intense infection of the subamniotic connective tissue and have demonstrated streptococci in the vessels on the fetal surface of the placenta and also in the umbilical vein. In another, streptococci were found in the placenta and in the cord, not in the lumen of the vein but in its wall. As further evidence that the cord infection proceeded from the placenta rather than the fetus no inflammatory lesion of the fetal respiratory or gastro-intestinal tract was found in any case. Various fetal organs were stained for bacteria but none were demonstrated.

It is also instructive that an examination of the placenta for bacteria occasionally serves to establish the cause of fetal death. Until this examination was made, the death of one infant which presented at necropsy a general peritonitis was attributed to imperfect nursery hygiene. Obviously, that explanation was excluded by the demonstration of streptococci in the placenta. Again, in the second case of placental bacteremia, the clinical diagnosis was hemophilia, and human blood serum was administered; the

9. Winckel: Quoted by Kronig, Note 5.

necropsy added nothing to the clinical findings. Also, in the third case the cause of the death of the fetus was not established clinically nor by postmortem; without appropriate study of the placenta the diagnosis could not have been made.

Placental bacteremia is not always attended by the death of the fetus or the newly born infant. This would not be expected. Bacterial invasion of the amnion and the chorion does not mean that the fetal blood vessels will necessarily become involved. The invasion may advance in another direction. Furthermore, the period of time elapsing between the invasion of the amnion and the birth of the infant may be too short for the organisms to reach the blood vessels in question. Clinical evidence corroborates this view; in cases of intrapartum fever, at most, two thirds of the infants perish.

This series of cases is not large enough to justify an uncompromising estimate of the part placental bacteremia plays in infant mortality. The fact, however, that three of twenty-seven deaths were attributable to this cause shows that it must be taken seriously into account. Perhaps it explains an appreciable number of the fetal and infant deaths heretofore impossible of explanation. Therefore, it is pertinent to recall the frequency of certain phenomena which are usually associated with bacterial invasion of the fetus.

Premature rupture of the membranes was noted by Bassett[10] five hundred times in 4,141 consecutive confinements and by Dmelin[11] four hundred times in 4,000 confinements. Thus, the frequency of this accident may be estimated to be between 10 and 15 per cent. On the other hand, Winckel and Krönig regard 3 per cent. as a fair estimate for the frequency of intrapartum fever. Basing a calculation on these statistics, it appears, if the membranes rupture prematurely, bacterial invasion of the placenta occurs in every fourth or fifth case. In view of these facts the routine study of the placenta for the purpose of demonstrating bacteria should be undertaken not only when the labor is febrile but also if it is prolonged after the membranes rupture.

Swimming-Pool Sanitation.—A valuable contribution to this subject is contained in *Public Health Reports*, Sept. 17, 1915. It is by W. A. Manheimer, Ph.D., of the Department of Bacteriology of Columbia University, and details in tabulated form the results of a bacteriologic study of the water of a number of pools under various conditions of use, without and with the use of a number of chemical disinfectants. Among the conclusions reached were that the cubic capacity of a pool affects its sanitary condition, pools of small capacity being more difficult to keep in a satisfactory condition even with the use of chemicals; the process of adding dilution water is an efficient means of reducing the bacterial content; the supervision of the plant and the class of attendance are also important factors in pool sanitation; filtration is an adequate means of clarifying the water, which is a means of preventing accidental drowning. In pools in which refiltration is not practiced the water becomes so cloudy in one day that the bottom of the pool cannot be seen; chemical disinfection with calcium hypochlorite is effective, but if added too infrequently or in too small quantity its value is largely lost. A trace of chlorin should be constantly present; the best method of keeping a pool in safe and sanitary condition is by the combined method of refiltration and chlorination.

A MODIFICATION OF THE ABDERHALDEN TEST *

J. BRONFENBRENNER, Ph.D.
M. J. SCHLESINGER, B.S.
AND
W. T. MITCHELL, B.S.
PITTSBURGH

In the course of the last two years the Abderhalden reaction has been brought to the attention of the medical profession so often that it is safe to assume that the fundamental facts discovered by Abderhalden are generally known. In short, Abderhalden, as does Ehrlich, assumes that normal cells of the body are able to assimilate only those substances present in the blood as its normal constituents. The changes brought about in the composition of the blood serum by introduction of foreign substances lead to disturbances in the processes of cellular nutrition and often to cellular death. The experimental study of the phenomena of assimilation of foreign material introduced directly into the blood stream revealed a number of facts pointing to the tendency of the cells to elaborate a special mechanism, by means of which the cells are able to protect themselves in a specific manner against the injurious effects of disturbances of their normal nutrition.

According to Abderhalden, this protective mechanism consists in the formation in the cells of new and specific ferments, which directly attack the foreign material. As in the case of the antibodies of Ehrlich, these specific ferments, according to Abderhalden's conception, at a certain stage of the process, may appear detached from the cells, and be found circulating free in the blood. The presence, in the blood of animals, of such specific ferments not existing there normally, may be taken to indicate that the parenteral digestion of foreign substances is taking place in the body. According to Abderhalden and his collaborators, the presence of such specific ferments may sometimes be demonstrated in the blood of experimental animals a few hours after the parenteral introduction of foreign substances.[1]

As Abderhalden has shown, not only foreign substances introduced experimentally, or these penetrating in the tissues as a result of infection, but also autogenous substances arising in the animal body under physiologic conditions may cause the production of specific ferments as soon as such substances find their way into the blood stream. Thus for instance, he found that during pregnancy the animal body elaborates specific ferments capable of digesting placenta protein.[2] This finding led Abderhalden to propose a new method of diagnosis of pregnancy, whereby the condition of pregnancy is suspected in every case in which the blood of the individual contains specific ferments that are capable of digesting placenta tissue in vitro.[3]

A great number of investigators confirmed Abderhalden's findings, and some of them attempted to apply the method to the diagnosis of various pathologic conditions.[4] They also found these ferments specific to such a degree, that they were able to differentiate by this method different closely allied species of bacteria.[5]

[2] Abderhalden, E.: Abwehrfermente, p. 91.

[3] Abderhalden, E.: Abwehrfermente, pp. 92, 93.

However, in spite of the great number of most enthusiastic supporters of the specificity of this method,[6] many investigators, continuously increasing in number, have not been able to fully confirm the usefulness of the method. According to some of them the reaction is absolutely devoid of specificity,[7] and others, whereas they acknowledge its value in negative cases as definitely excluding the presence of specific ferments, deny the value of positive findings;[8] others, again, think that the ferments are only relatively specific, namely, their specificity is directed toward groups of substances, but not toward the individual members of each group.[9]

Referring to these differences in opinion of different investigators, Abderhalden repeatedly stated that those unable to repeat his experiments are undoubtedly using a faulty technic, and until they obtain the expected results, they ought not to consider themselves in possession of the knowledge of the method.[10] On the other hand, Oeller and Stephan, for instance, from their experience with the test, concluded that the reasons for the discrepancies are much deeper—they believe that the study of protective ferments has already come to the point at which "further progress is possible only if the whole mass of contradictory clinical results obtained up to date is thrown overboard, and the study of the problem is started anew."[11] These authors found that although under certain conditions of the experiment the Abderhalden method gives suggestive results, still the further systematic study is impossible until we do away with such parts of the technic of the method as are responsible for the errors in the result.

Although many authors are inclined to think that the technic of the Abderhalden test is very difficult,[12] our own experience showed us that the method is much simpler than some other serologic methods. The difficulty in obtaining more constant results, lies, as we see it, not so much in the complexity of manipulations, as in the fact that the relations of the ingredients to each other are not properly understood, and, therefore, are not properly controlled in the test.

Our experiments have shown us that although in a number of cases one obtains apparently specific results, the Abderhalden reaction does not depend on the presence in the serum of specific ferments.[13] The very fact that these ferments, according to Abderhalden, appear almost immediately on introduction of foreign material, made many authors doubt the possibility of their existence.[14] Moreover, the fact that a certain number of male serums in the hands of reliable workers give rise to dialyzable split products when combined with placenta shows that the digestive properties of serum may not be specific.

In our own experiments conducted with the view of detecting the nature of the Abderhalden reaction, we came to the conclusion that in no case is the placenta digested,[15] and that the mechanism of the reaction is entirely different from that ascribed to it by Abderhalden. Namely, we found that, as first suggested by Stephan and Hauptmann,[16] the Abderhalden test is possible only with the serums containing complement, and when complement is missing, any fresh serum is able to activate the test,[17] thus showing that at least the active principle in the digestion is not specific. Moreover, it was found that the relative specificity of the test depends not on the presence of specific ferments, but on the substances, which, like the antibodies of Ehrlich, are not active by themselves, but are responsible for the specificity of the reaction.[18] We found, further, that the active principle responsible for the appearance of the dialyzable substances is, like complement, present in every fresh serum, and possesses properties of a tryptic ferment. This ferment is normally prevented from exhibiting its digestive power by the simultaneous presence in every serum of inhibiting substances apparently colloidal in nature. These under the influence of the physiochemical changes in the medium occurring during the experiments, easily lose their property to neutralize the trypsin of the serum.[19] Such changes are most easily produced through adsorption. For instance, addition to a fresh serum of a suitable amount of any organic substratum or of substances like kaolin, starch, agar, etc.,[20] changes the degree of colloidal dispersion in the serum, and the normal trypsin is set free. Although, as we have shown,[21] if such nonspecific tryptic ferment liberated from the serum is able to digest natural protein (bacteria, placenta cells, etc.), it is, however, absolutely unable to attack a denatured coagulated substratum. It is thus that we concluded that in the Abderhalden reaction the dialyzable split products originate not from the boiled substratum, but from the serum itself.[18, 19]

[20] This phenomenon was noticed also by previous observers (Plaut: München. med. Wchnschr., 1914, p. 238. Kjargaard: Ztschr. f. Immunitätsforsch., xxii, 31. Herzfeld: Biochem. Ztschr., 1914, p. 1. Peiper: Deutsch. med. Wchnschr., 1914, xl, 1467. Flatow: München. med. Wchnschr., 1914, lxi, 1168).

[21] Bronfenbrenner and Scott: Proc. Soc. Exper. Biol. and Med., 1915, p. 137.

Experiments show that the number of positive reactions, obtained with specific serums, is much higher than that obtained with normal, although the substratum in the Abderhalden reaction is not digested, and the dialyzable substances originate from autodigestion of the serum under examination. Many authors who ascribe the digestion in Abderhalden reaction to nonspecific ferments, have suggested that the apparent specificity of the test must be due to the fact that during pregnancy as well as in different pathologic conditions, the serum contains a larger quantity of proteolytic enzyme than normally, and thus gives a higher percentage of positive reactions.[22]

Our own experiments, however, suggest another explanation. Whereas an excess of substratum is able to set to autodigestion any fresh serum, in an absolutely nonspecific manner, a suitable amount of substratum as prescribed by Abderhalden will very often react only with specific serums. It is thus possible that the reaction is specific when certain definite quantitative relations are maintained between the substratum and the serum, it is certain, however, that an excess of substratum will exert a nonspecific adsorption on any fresh normal serum. The experiments performed with the view of studying this possibility showed that boiled substratum, similarly to any antigen, is able to extract from the specific serum its antibody, and as a result this substratum is so changed that it is now able to adsorb from the fresh serum its antitrypsin and thus set free trypsin (Table 1).

Substratum is allowed to remain in contact with specific serum in a centrifuge tube on ice for sixteen hours, as before. Then the contents of the tube are centrifuged and the substratum is separated *from the serum. The substratum is now* washed, suspended in salt *solution, and placed* in a dialyzing thimble, and the serum, separated from it, is placed in another thimble and returned to the ice box for sixteen hours. As the table shows, no dialyzable substances appeared in either case. If, however, both thimbles were now transferred to *37* C., the serum gives *off products* of self-digestion, while the substratum does not show even traces of it. However, according to the hypothesis suggested, such a substratum must have acquired the property of removing from the serum the substances inhibiting the activity of the ferment in the serum. *To ascertain* if this was the case, the same substratum was separated from salt solution and placed in contact with fresh normal serum in a new thimble (Table 1, *A*). Whereas the normal serum used in this experiment, when placed in contact with fresh substratum, gave a negative Abderhalden test (*Table* 1, *C*), the same serum, being placed in contact with the substratum previously treated with specific serum, and from which all traces of the serum were washed away, gave a distinct ninhydrin reaction (Table 1, *A*).

The experiments reported in Table 1 thus show that within certain quantitative limits the Abderhalden reaction remains specific, but if the substratum is taken in excess, it may act mechanically and the reaction becomes nonspecific.[23]

It is thus apparent that the Abderhalden reaction consists of two consecutive phases. *In the first phase* of the reaction the antigen of the substratum unites with the antibody of the specific serum, and in the second phase such a "sensitized substratum" adsorbs antitrypsin and permits autodigestion of the *serum*. By preventing fresh serum from autodigestion immediately following the sensitization of the substances we actually separated the two phases.[24].

Using the known property of antibody to unite with antigen at low temperature, which prevents the activity of the complement and also excludes the activity of the proteolytic ferment, we found that the thimble containing placenta and pregnant serum did not give up dialyzable substances into the surrounding medium.

[22] Solowjew: Zentralbl. f. näk., 1914, No. 17. Kjargaard, Ztschr. f. Immunitätsforsch., 1914, xxii 1. Flatow: München. med. Wchnschr., 1914, p. 1500.

[23] It is important to remember that the suitable amount of substratum, acting specifically with one serum may be unsuitable for another serum, and here is the main weakness of the method.

[24] Bronfenbrenner, Mitchell and Schlesinger: Biochem. Bull., April, 1914, p. 386.

We did find, however, that the placenta, as well as the serum, underwent changes very similar to those we should have expected if we had used a hemolytic amboceptor and corresponding erythrocytes, namely, placenta protein had adsorbed the antibody from the serum and the serum lost all its specific properties. The summary in Table 2 gives the essentials of our results.

These findings are not only of theoretic importance, inasmuch as they furnish further proof of the similarity of the phenomenon described by Abderhalden to immunity reactions in general, but are also of practical value. Those making routine examinations by the Abderhalden method, know that the blood of a patient taken under certain conditions may contain an amount of amino-acids sufficient to mask the specific reactions,[25] as for instance, when the patient has high temperature, when there is pus formation, or if the patient has recently partaken of food. Whereas, the last mentioned factor can be regulated with but little inconvenience to the patient, the blood being taken before breakfast, it is impossible to obviate the complications in other cases.[26] In such instances where the serum itself contains dialyzable ninhydrin reactive substances, the difference in the intensity of the reaction with ninhydrin in the control tube, and in the tube containing substratum as well as serum, furnishes the basis for diagnosis, but undoubtedly this may be a source of errors.[27] A modification was offered therefore, by Schlimpert,[28] who removes this source of error by subjecting the serum of the patient to dialysis prior to application of the test proper, using subsequently such serum deprived of its dialyzable material for the digestion with placenta.

	Substratum (sensitized?) with 1.5 c.c. normal serum
	In thimble at 37 C. for sixteen hours
	Ninhydrin test —

Our own study suggests another possible modification of the procedure of Abderhalden which would take advantage of the property of the substratum to become sensitized by the specific serum, so as later to give up dialyzable substances when placed in contact with any fresh human or animal serum. Such a method would permit the examination of serum taken at any time, no matter what the condition of the patient might be. The procedure is the following: After remaining over night in contact with suspected serum in the ice box, placenta (or any other substratum as the case may be) is centrifuged, washed with water to remove any serum which may adhere to it, and placed in a new thimble with any fresh serum that happens to be on hand. The best for this purpose is serum from a guinea-pig kept without food long enough (from six to eight hours) to free its blood from dialyzable ninhydrin reactive substances. It is necessary of course to take the additional precaution in examining for pregnancy, of using male guinea-pig serum, since fresh serum from a female guinea-pig which may happen to be pregnant may give a positive reaction when combined with placenta in the test, and this may cause grave error.

CONCLUSIONS

Abderhalden tests depend on the presence in the serum of specific substances which are not of a fermentive nature.

The substratum is not digested during the test.

Dialyzable split products originate from the serum as a result of its autodigestion, and not from the substratum.

Analysis of the test shows that it consists of two phases, and this gives a basis for a useful modification of the method.

PANCREATIC FERMENT DETERMINATION IN PULMONARY TUBERCULOSIS *

ETHAN A. GRAY, M.D.
Medical Director, Chicago Fresh Air Hospital; Attending Physician, Augustana Hospital
AND
OLGA PICKMANN, M.D.
Assistant Chicago Fresh Air Hospital
CHICAGO

Much attention has been given to the diet of the tuberculous. Quality and daily quantity have received consideration. Digestive disturbances, as expressed by anorexia, vomiting, dyspepsia (gastric distress), intestinal indigestion and diarrhea have long been recognized as forming parts of the general picture in tuberculosis.

In the absence of gross signs of digestive derangement, it is not unusual to see a patient eat well but fail to gain in weight. It is common to see a tuberculous patient refuse all food, especially when the system is under the influence of toxins; this may be in the early febrile period as well as in the terminal stage.

Again, we see patients with good appetites and high temperatures — far advanced patients, with no appetites and low temperatures.

Observing over 200 cases, we found that, as is well known, our patients preferred vegetables and starches; that they consumed foods of these types much in excess of body needs and their ability to digest, and that starch was passed in the feces, chemically unchanged — not alone in recognizable particles as, for example, potato, but also in the fecal mass, to be ated from the serum is able to digest natural protein (bacteria, placenta cells, etc.), it is, however, absolutely unable to attack a denatured coagulated substratum. It is thus that we concluded that in the Abderhalden reaction the dialyzable split products originate not from the boiled substratum, but from the serum itself.[18, 19]

[26] The presence of dialyzable material in the fluid in which the specific ferments are looked for, is especially important in the examination of urine, in which there is always a certain amount of such substances present.

* Read before the National Association for the Study and Prevention of Tuberculosis, Seattle, June 16, 1915.

Experiments show that the number of positive reactions, obtained with specific serums, is much higher than that obtained with normal, although the substratum in the Abderhalden reaction is not digested, and the dialyzable substances originate from autodigestion of the serum under examination. Many authors who ascribe the digestion in Abderhalden reaction to nonspecific ferments, have suggested that the of substratum will exert a nonspecific adsorption on any fresh normal serum. The experiments performed with the view of studying this possibility showed that boiled substratum, similarly to any antigen, is able to extract from the specific serum its antibody, and as a result this substratum is so changed that it is now able to adsorb from the fresh serum its antitrypsin and thus set free trypsin (Table 1).

The experiments reported in Table 1 thus show that within certain quantitative limits the Abderhalden reaction remains specific, but if the substratum is taken in excess, it may act mechanically and the reaction becomes nonspecific.[23]

It is thus apparent that the Abderhalden reaction consists of two consecutive phases. In the first phase

...ation. This represents 5,000 units.
The average normal reading is from 500 to 1,000.
To make the test, fecal solutions of 1:10, 1:100
and 1:1,000 are made and poured into nine test tubes
as follows: First three tubes: 1:10 solution, 2, 1
and 0.5 c.c. starch solution 1 per cent., or casein
solution 1:1,000. Second three tubes: 1:100 solu-
tion, 2, 1 and 0.5 c.c. Third three tubes: 1:1,000
solution, 2, 1 and 0.5 c.c. To each tube are added 5 c.c.
of 1 per cent. soluble starch solution or 1:1,000 casein
solution, as the case may be. The tube showing diges-
tion, that is, no reaction, by the weakest fecal solu-
tion after twenty-four hours' incubation, is taken as
the index of digestion. The casein reagent is, as pre-
viously indicated, acetic alcohol (1 per cent. acetic acid
may be used); the starch reagent is Lugol's solution.
A large number of the cases examined showed no
free amylopsin. This does not mean that no amylopsin
had been secreted, but that all secreted amylopsin had
exp... neutralized by the starch excess (Cases 4, 6, 7, 8
to se...). We should, therefore, disregard zero amyl-
lutely ...readings until we estimate the starch intake.

PROTOCOL

The protocols show trypsin and amy... reduced in the tuberculous under influence of toxins. In favorable cases, disappearance of toxin is accompanied by increase of trypsin. Amylopsin is less frequently found because of the excess of starch found in the feces of the tuberculous; the ferment is neutralized by this excess. Trypsin indexes may be large in presence of anorexia and gastro-intestinal complications by lack of protein neutralization; also, because of actual improvement. Constantly low trypsin index is present in failing cases. Rising index with good appetite is favorable.

Case 1.—Frida S. Far advanced.

Oct. 30, 1914, amylopsin, 10,000; no trypsin demonstrable. Absolute anorexia. Death. No food intake, and hence no neutralization of ferments. Therefore, high amylopsin reading.

Case 2.—Percy K. Terminal.

Oct. 25, 1914, amylopsin, 100; trypsin, 500. Diarrhea (tuberculous).

Dec. 31, 1914, amylopsin, 25; trypsin, 10,000. Death.

Diet was fluid, chiefly; some starch, no protein, hence high trypsin readings, due to non-neutralization.

Case 3.—May S. Far advanced.

May 30, 1914, amylopsin, 700; trypsin, 100. Weight, 118½. Anorexia.

July 25, 1914, artificial pneumothorax. Weight 118¾.

Oct. 15, 1914, amylopsin, 25; trypsin, 5,000. Weight, 129¼.

Oct. 29, 1914, amylopsin, 50; trypsin, 10,000. Weight 135. Convalescent.

---

31. F...
...th. u. Therap. d. Ernährungs-

Intake, starches, no protein. After artificial pneumothorax, appetite for meat increased, weight increased, trypsin increased. Here, lung collapse reduced toxemia, and thus freed the digestive system from the influence of infection.

Case 4.—Margaret S. Far advanced.

March 2, 1915, amylopsin, 100; trypsin, 100. Weight, 93½.

March 5, 1915, pneumothorax (bilateral and extensive).

April 15, 1915, amylopsin, 0; trypsin, 5,000; general diet.

April 17, 1915, amylopsin, 0; trypsin, 100; 100 gm. protein.

April 19, 1915, amylopsin, 0; trypsin, 25; 250 gm. protein.

April 21, 1915, amylopsin, 0; trypsin, 0; 300 gm. protein. Weight, 89.

Losing ground; daily fever.

This was a bilateral, febrile case; appetite fair, worse lung collapsed to reduce septic absorption; fever dropped somewhat, cough and sputum ceased. April 15, the determinations were made on a general diet, which was chiefly starch; very little protein. In quantitative test, 100 gm. protein reduced the trypsin reading to 100 units, 250 gm. to 25 units, while 300 gm. entirely neutralized the secreted trypsin. Patient losing ground; febrile.

Case 5.—William S. Far advanced. Diabetes with tuberculosis. Protein diet.

Oct. 17, 1914, amylopsin, 50; trypsin, 0; wasting.

Starches given; weight gain at once. General improvement until influenza, bronchopneumonia, death.

Jan. 12, 1915, amylopsin, 0; trypsin, 100. Mixed diet. Death.

Case 6.—Hannah S. Far advanced. Weight on admission, Dec. 1, 1914, 107¾. No trypsin. Bed rest one month.

Dec. 12, 1914, amylopsin, 100; trypsin, 0.

Jan. 7, 1915, amylopsin, 0; trypsin, 100. Weight, 119 (a gain of 11 pounds); appetite better.

Jan. 13, 1915, pneumothorax. Trypsin index steadily rose after this.

Feb. 5, 1915, amylopsin, 0; trypsin, 0. Weight, 120. Appetite good.

March 3, 1915, amylopsin, 0; trypsin, 250. Weight, 122.

April 24, 1915, amylopsin, 100; trypsin, 1,000; 100 gm. protein.

April 26, 1915, amylopsin, 0; trypsin, 5,000; 250 gm. protein.

April 28, 1915, amylopsin, 0; trypsin, 10,000; 300 gm. protein.

General condition excellent.

Case 7.—Howard C. Far advanced. Weight, 122. Fever. Anorexia.

Jan. 5, 1915, amylopsin, 0; trypsin, 1,000. Weight, 117. Gastric distress.

March 22, 1915, amylopsin, 0; trypsin, 100. Weight, 116¾. No fever.

April 23, 1915, pneumothorax. Weight, 116¾. Fever.

May 1, 1915, amylopsin, 0; trypsin, 250. Weight, 117. General diet.

May 2, 1915, amylopsin, 0; trypsin, 10,000; 100 gm. protein.

May 3, 1915, amylopsin, 0; trypsin, 250; 250 gm. protein.

May 5, 1915, amylopsin, 0; trypsin, 1,000; 300 gm. protein.

No fever since pneumothorax. Weight, 125. Appetite good.

This patient was wasted, febrile and dyspeptic. Four months of rest in bed led to little improvement. Then pneumothorax on the worse lung was followed by almost instant change for the better; gastric symptoms disappeared. Trypsin index, May 1, was 250 units. May 2, the protein diet was reduced to 100 gm., resulting in a trypsin index of 10,000, with 300 gm. protein. May 5, trypsin was 1,000 units, or double the normal.

Case 8.—Hugh C. Far advanced.

Nov. 14, 1914, amylopsin, 25; trypsin, 50.

Jan. 5, 1915, amylopsin, 0; trypsin, 25.

March 6, 1915, amylopsin, 0; trypsin, 50. Bedfast.

Case 9.—Hannah P. Far advanced.

Nov. 20, 1914, amylopsin, 100; trypsin, 250. Weight, 136¾.

Dec. 23, 1914, amylopsin, 0; trypsin, 250. Weight, 137¼.

Feb. 1, 1915, amylopsin, 0; trypsin, 50. Weight, 134¼.

Feb. 19, 1915, pneumothorax.

March 6, 1915, amylopsin, 0; trypsin, 0. Weight, 135. Invalid.

Cases 8 and 9 both show low trypsin indexes. Both are far advanced. Both have extensive lung involvement. Patient 8 has been for many months confined to bed. Patient 9 has had fever from time to time, and is now an invalid.

These constantly low trypsin readings are the rule in far advanced cases not presenting any gastric or intestinal disturbance.

Case 10.—Vivian K. Incipient. Weight, 106.

Jan. 23, 1915, amylopsin, 0; trypsin, 0. Weight, 108.

Feb. 20, 1915, amylopsin, 0; trypsin, 250. Weight, 110½.

Case 11.—Violet I. Incipient.

Feb. 10, 1915, amylopsin, 0; trypsin, 0. Stomach pain after eating.

March 10, 1915, amylopsin, 50; trypsin, 25. Weight, 132.

May 20, 1915, weight, 130.

Generally better. Eats well.

Cases 10 and 11 are both closed cases, with poor appetite and poor digestion; prolonged bed rest brought improvement in both.

CONCLUSIONS

1. Pancreatic secretions are seriously diminished by toxins of tuberculosis, in any stage.
2. Rest (bed rest or pneumothorax), by reducing the production of toxins, aids in the return to a normal of these pancreatic secretions.
3. Persistently low trypsin readings are prognostically bad.
4. Low amylopsin values are of lesser prognostic importance.
5. All interpretations of indexes must be made with due consideration for anorexia, overeating and diarrhea.

2733 North Clark Street.

THE USE OF A LOAN COLLECTION AND PHOTOMICROGRAPHS

IN THE TEACHING OF PATHOLOGY TO STUDENTS OF MEDICINE *

ERNEST SCOTT, M.D.
AND
JONATHAN FORMAN, M.D.
COLUMBUS, OHIO

Perhaps one of the most obvious defects in the usual method of teaching pathology lies in the restrictions which are imposed on the student. Too often the method is such that all he can do is to memorize certain statements of the textbooks and instructors, and to fix in his mind the appearance of certain slides rather than to read the cell changes going on in the tissues and thereby gain a plastic living conception of the processes at work in the specimen being studied.

It is generally recognized that the method rather than any particular content is the essence of scientific discipline. As Oertel[1] says:

"Medical education is primarily directed toward the development of the powers of observation and of a scientific method of thinking." One of the chief problems, therefore, in offering a course in pathology is to present it so that the student may be able to visualize the processes and at the same time keep the theoretical explanations separate from established facts and from

---

* From the Department of Pathology and Bacteriology of the Ohio State University, College of Medicine.

[1] Oertel, Horst: The Anatomic Histological Processes of Bright's Disease, Philadelphia, 1910, p. vii.

his own observations. This must be done with minimum loss of time and energy. The time which can be allowed pathology in the medical curriculum is, at best, altogether too short. Every minute must be used, therefore, with the greatest degree of efficiency.

It is the purpose of this paper to give an account of the method in use in the laboratory of pathology at the Ohio State University, College of Medicine, in the course offered to second-year students of medicine. the use of a loan collection and photomicrographs, lution has been reached, to a certain extent, at for the problems outlined above.

ormerly much time was consumed in the mounting and staining of sections. This was cut down somewhat by staining the sections before handing them out to the class. The giving out of sections to all the members of a class each year necessitates the use of some rather indifferent material. For, as Dr. Mallory[2] says, "It requires patience often extending over many years to collect the tissues most suitable for study and teaching purposes." If this is true in the larger medical centers, it is the more applicable elsewhere. Further, the time consumed in the preparation and sketching of sections limits very decidedly the amount of work which can be covered in the time allowed to pathology in the medical curriculum.

Experience has taught us to agree with Drs. Steenland and Weiskotten[3] that much valuable time may be saved and much better preparations can be presented by the use of a loan collection. On the introduction of such a collection, we were able to increase the number of slides studied over 50 per cent. This, therefore, not only gives an opportunity to present slides typical of the various lesions which could not be introduced into the course before on account of a lack of time, but also allows the introduction of more stages in the development of the lesions than could be taken up with the student under the previous method. In this way the lesions can be traced in their development from the simplest to the most complex. The presentation in this way of the subject in its order of sequence gives the student training in the analysis of biologic problems. This training will stand him in good stead later in the study of clinical cases in which he will meet the same consequents and their causal antecedents. The use of this method affords the student a larger experience and, what is more important, it presents to him more of the evidence on which conceptions of pathologic processes have been built in the past. In this way he gains a sense of the reality of his own conceptions. The subject of pathology becomes something more than a series of dry facts to be memorized. It becomes a living process.

It may seem that this works a hardship on the student by depriving him of his collection of pathologic sections, but the man who will really need a personal collection after the course is finished is the man who is especially interested in the subject. If the student "goes in for pathology," he must do more work than is covered in the regular courses of the medical curriculum. In that case the advanced work will give him ample opportunity to make his own collection, and a collection made in this way will have far more value to him than one which has been prepared for him.

The sketching of a microscopic preparation is very apt to become a mechanical process unless each student is given a great deal of painstaking, personal attention, and at best it consumes much time. In our laboratory, this time has been utilized in another way and with better results for our classes. As stated before, photomicrographs have been made of the important areas in each section. Each student in the last four classes taking the work has been given a set of these photographs to be pasted in his laboratory notebook.

In making these photomicrographs, the degree of magnification has been determined for each section. Where it is advisable to show the cellular elements out of which the lesion is built, a high dry or 1.9-mm. oil immersion lens is used; where it would appear better to orient the student first and then allow him to work out the cytology for himself, a 16-mm. lens is employed, and the fields to be given special attention are marked on the photograph. Even with the higher magnifications, it is of advantage to have the important areas marked in such a way that the student may locate them readily and indicate them specifically in his notes.

The method of conducting the class in the laboratory is to give out the numbers of the slides to be studied (the organ or injurious agent whose reaction is to be considered having been previously assigned). After the section, together with the photograph and the text has been studied by the class, an informal quiz is given. Various members of the class are called on to give their interpretation of the processes under consideration, and a description of the areas or cellular elements which are marked on the photograph. The remainder of the class follow the progress of the student being quizzed by observing their own sections, photographs and notes, making such corrections in the latter as they deem necessary. After the quiz is over, the demonstrators pass around the class in an endeavor to clear up such obscure points as may be necessary for the individual student. Frequent slide reviews are given in which "unknown" sections are used. Free access is allowed to textbooks, notes and other references. Often the gross specimen or an abstract of the case record or both are given out with the sections. The student is required to write his description and interpretation of the cases under consideration. The papers are then read and discussed with the class.

By this method, the student has most of his time for study and the correlation of the conditions observed in his specimens. Another advantage found in the use of the photomicrographs is that in the recitation definite objects are under consideration, and the discussion can be limited to an accurate description which every one can readily follow.

By this method, we have been able to increase the amount of work covered about 60 per cent., or about 110 per cent. over that which was covered before the introduction of the loan collection and photomicrographs.

The saving of time in this way allows not only for introduction of various experimental demonstrations fashioned after the suggestion of Professor Pearce,[4] but also for the exhibition of many more gross specimens illustrating the anatomic lesions at the same time that the histologic changes are being studied. It also permits of more frequent slide reviews, which are of great value in stimulating the students to make more careful observations.

---

[3] Steenland, H. S., d Weiskotten, H. G.: The Histologic Loan Collection and Relieving he Curriculum, The Journal A. M. A., Jan. 10, 1914, p. 125.

[4] Pearce, Richard M.: The Teaching of Experimental Pathology and Pathological Physiology to Large Classes, Bull. Johns Hopkins Hosp., 1912, xxiii, 170.

The laboratory notebooks obtained by this method are in every way superior to the ones which had been obtained formerly. At the end of his course, the student possesses a manual in which the photomicrographs have been neatly mounted, beneath which there is a brief but careful description of the lesion pictured, together with an abstract of the textbooks and the lectures. Such a manual possesses considerable value to the student as a work of reference. This method, used as a routine in the laboratory, has met and overcome several of the objections usually raised to the course in pathology. It has secured greater application on the part of the students during the laboratory periods, a greater amount of outside reading, more concise and accurate descriptions in the notebooks, and increased efficiency in the slide reviews.

No doubt there is a valuable training to be derived from the sketching of histologic preparations by the student, but we are convinced that the sacrifice of time is too great for its employment in the regular course in pathology offered to second-year students of medicine. In those courses in which accurate observation of fixed morphologic structures is the important thing, as it is in normal histology, sketching should be employed; but in pathology it is more important that the student should develop the ability to give an accurate word picture, and still more important that he should be trained to visualize the changes taking place so that they become a living progressive process to him.

The labor and expense attached to such a method are not excessive. After the negatives are made, the prints may be done by a professional photographer, who can be induced to do large lots at a very reasonable rate. The photographs can be sold to the student at cost, and the price will not exceed that of laboratory books in the other branches. The cost can still further be reduced, we have found, by the use of engravings made from the photomicrographs.

Students, of course, are given the privilege of making a collection of slides for themselves, and it has so chanced that with each succeeding class trained by this method, more men are preparing their own collections. Only those men in whom a real interest for pathology has been aroused avail themselves of this opportunity.

SUMMARY

The use of the loan collection and photomicrographs in the teaching of pathologic histology possesses the following advantages:

1. It compels the student to write concise and accurate descriptions of the specific cellular elements and of the lesions which they build up.
2. It allows the discussion or quiz to be followed in detail with much greater ease.
3. It gives time for the introduction of more experimental demonstrations.
4. It permits of closer correlation between the gross and the histologic pathology.
5. It enhances the value of the notebook.
6. Most important of all, it opens a greater opportunity for the student of medicine to do some thinking for himself.

ORBITOPALPEBRAL EMPHYSEMA CAUSED BY PERFORATION OF A DENTAL CANAL

AARON BRAV, M.D.
Ophthalmologist to the Jewish and Lebanon Hospitals
PHILADELPHIA

Orbitopalpebral emphysema is not a very common condition, but when it is found it is always of traumatic origin. Ordinarily it is the result of a fracture of the nasal, lacrimal or ethmoidal bones. It may, however, occasionally be caused by the dentist during the process of drilling the dental canal, as can be seen from the case which I here report. The condition is practically harmless and requires no treatment beyond a pressure bandage.

The diagnosis of the condition is comparatively easy. There is a sudden swelling of the lid and adjacent tissues, with no signs of inflammation, no redness, no pain. The swelling does not pit on pressure, but quickly rebounds, and there is a peculiar crackling sensation felt by the palpating finger, which results from the movement of air bubbles under the fingers. There is no exophthalmos in this variety of emphysema. Exophthalmos is present in emphysema of the orbit, but not in emphysema of the lid. Properly speaking, this form of emphysema should be termed "palpebrofacial," for usually the face is involved in the edema in addition to the lids. None of the textbooks mention mechanical perforation of the dental canal as a possible cause of emphysema, therefore this case should be placed on record.

Miss L. came to me accompanied by her dentist, who gave me the following history. While drilling on the mesial root of the right upper first bicuspid tooth he felt as if his burr entered a vacuum. He then tried to explore the region with a broach, which went in for a considerable distance. During this operation the patient felt no pain except some pressure sensation, which she attributed to the pressure of the dentist's thumb on her cheek. When the broach was withdrawn her lids suddenly began to swell, so much so that the right eye was entirely covered by the swelling of the upper and lower lids. The swelling spread all the way down the face and even the neck. I saw the patient about an hour and a half after, and found the face swollen, the lids, very markedly edematous, covering the right eye. The lids, however, could easily be separated. The asymmetry of the face as a result of the unilateral swelling gave the patient a hideous appearance. The skin of the lids and face was not tense and had no signs of inflammation. There was no pitting on pressure as the skin quickly rebounded. There was, however, marked crepitation under the finger's touch all over the lids and face and even down the region of the neck. Sneezing or blowing the nose had no influence on the swelling. My diagnosis was of course clear and easy: Palpebral emphysema caused by perforation of the dental canal into the antrum of Highmore and the upper bony roof of the antrum, through which the air must have gone into the subcutaneous tissues. This condition could easily be differentiated from a cellulitis by the sudden onset and the absence of inflammatory symptoms, such as redness and pain, and, of course, by the crackling sensation under the finger.

I applied a pressure bandage and the next day the swelling was considerably less. On the fifth day, while the swelling was practically all down, there was still present a slight crackling sensation indicating that not all the air had been absorbed. Seven days elapsed before all the symptoms disappeared. No other treatment was given except the pressure bandage for two days.

AN UNUSUAL TYPE OF GROSS CARDIAC ARRHYTHMIA *

PAUL D. WHITE, M.D.
BOSTON

Gross irregularity of the pulse signifies, as a rule, that fibrillation of the auricles is present with the resultant ventricular arrhythmia. Rarely a gross sinus arrhythmia not dependent on respiration or an auricular flutter with irregular grades of heart-block may produce a condition of the pulse simulating that of auricular fibrillation.

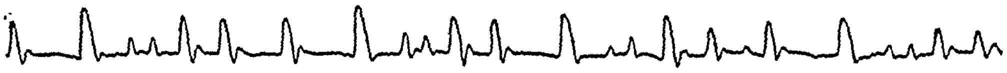

Fig. 1.—Radial pulse tracing showing marked arrhythmia. Time interval, 0.2 second.

In the case here described, an unusual cause of the gross arrhythmia was found, consisting of a curious aggregation of ectopic contractions arising from at least three different points in the ventricles, with now and then an aberrant beat of supraventricular origin slipping in (Figs. 1 and 2). The time intervals between the ventricular complexes are shown below the electrocardiogram. On several occasions while the patient was under observation at the Massachusetts General Hospital this arrhythmia was found. At other times there occurred a bigeminy due to ventricular premature beats alternating with the beats of supraventricular origin (Fig. 3). Rarely a short run of beats of normal rhythm occurred, and on such occasions pulsus alternans was found to be present. Electrocardiograms showed the existence of defective conduction in the right branch of the atrioventricular bundle.

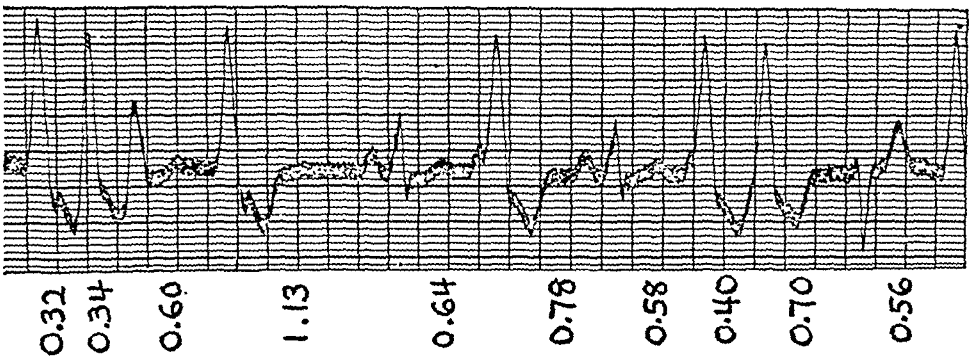

Fig. 2.—Electrocardiogram, Lead II, showing eleven ventricular complexes, of which nine are ectopic and only two produced by the cardiac impulse arising in the auricle. These two beats of normal rhythm are aberrant, that is, distorted, as the result of a damaged atrioventricular conducting system. Below the electrocardiogram there are recorded the measurements in fractions of a second of the intervals between the ventricular complexes. Abscissa, 0.2 second; ordinate, 10^{-4} volt.

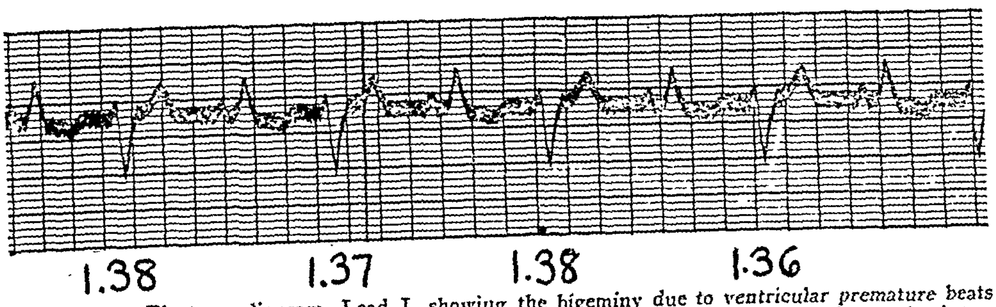

Fig. 3.—Electrocardiogram, Lead I, showing the bigeminy due to ventricular premature beats alternating with the beats of normal rhythm. Below the electrocardiogram are shown the intervals in fractions of a second between the beats of normal rhythm. Abscissa, 0.2 second, ordinate, 10^{-4} volt.

CLINICAL RECORD

History.—F. H. R., man, aged 61, married, packer in a candy factory, entered the wards of the Massachusetts General Hospital, April 8, 1915, for the relief of dyspnea and spells of weakness. Family and past history were unimportant save for the fact that his wife had had two miscarriages. One son was living and well. Patient denied venereal disease. No alcohol or tobacco was used.

The present complaint begins with the story that twelve years ago while walking home from work he fell unconscious in the street and was taken to a hospital, where he remained for three hours, rapidly recovering his senses and strength. He was told at that time by the doctors that he had "heart trouble and must take things easy." Ever since this experience the patient has noticed that he has been dyspneic on exertion. Six weeks before admission to the hospital the dyspnea increased so that he became short of breath on slight exertion. Four weeks later he was seized with an attack of syncope lasting half an hour shortly after he had carried a hod of coal up a flight of stairs. Following this attack he became more dyspneic, and suffered severe epigastric pain necessitating his staying in bed during the week following. For the four or five days just preceding admission to the hospital he had somewhat improved.

Physical Examination.—The patient was lying comfortably flat in bed without dyspnea or cyanosis. Pupils reacted sluggishly to light. Heart enlarged; apex in the sixth interspace, transverse measurement of heart by Roentgen ray, 17 cm.; width of great vessels at second space, 5.5 cm.; systolic murmur heard over precordia, reduplication of second sound at base. Pulse irregular (Fig. 1). Liver not enlarged. No edema of lungs or extremities.

Clinical Observations.—Blood pressure, from 145 to 150 mm. Hg systolic, and from 70 to 90 diastolic. Urine normal. Blood normal. Wassermann test negative. Spinal fluid normal. No fever. Respiratory rate from 19 to 28 per minute. Pulse rate from 90 to 110 per minute.

The effect of exercise, atropin (1/10 grain subcutaneously), and vagal pressure on the cardiac arrhythmia was tested, but no change in the degree of irregularity was observed. April 24, 1915, the patient left the hospital feeling somewhat improved after his sixteen days' rest in bed. No digitalis was given. July 15, 1915, an electrocardiogram showed a bigeminy very similar to that of Figure 3, but at times interrupted by numerous ectopic ventricular contractions.

SUMMARY

An instance is recorded of periods of gross cardiac arrhythmia due not to auricular fibrillation or sinus arrhythmia but to an unusual combination of ectopic ventricular contractions.

TRICHINOSIS SIMULATING FRONTAL SINUSITIS

A REPORT OF THREE CASES

EDWARD L. PRATT, M.D.
Assistant Visiting Surgeon, Vanderbilt Clinic, Department of Laryngology
NEW YORK

During the past two years I have seen three cases of trichinosis, each referred as a probable case of frontal sinusitis. Two of these cases were seen in private practice and the third was referred to the Department of Laryngology at the Vanderbilt Clinic.

As is well known, the symptomatology of trichinosis is most variable. Most textbooks emphasize its resemblance at the onset to typhoid fever and its symptoms are usually classified under (1) intestinal or choleriform stage; (2) rheumatic or typhoid phase. It sometimes simulates appendicitis and is frequently called "rheumatism" — that facile term so often connoting only our ignorance. From a fairly comprehensive search of the literature I find no mention of cases simulating frontal sinusitis.

Case 1.—Mrs. B. R., aged 31, a physician's wife, was first seen with Dr. C. G. Coakley, Feb. 10, 1913. The patient at that time complained of a severe "cold in the head," excessive thick nasal discharge from both nares, and headache. Duration, three or four days. Examination revealed infection in both maxillary antrums. The antrums were cocainized and punctured beneath the inferior turbinates and a large amount of thick mucopurulent secretion was washed out of both antrums. The antrums were washed out daily for about ten days, when the patient was discharged cured. Patient remained apparently well until March 15, 1913, when she began to have pain in and about the left eye and left frontal region. In view of the fact that she had but recently recovered from an infection in her antrums, her husband suspected that she might have frontal sinusitis and sent her in to the office. Examination of the nares revealed only a slight amount of congestion of the mucous membrane. Transillumination of the sinuses showed that the left frontal sinus illuminated well over a moderate sized area; the right frontal illuminated poorly over a very small area; the antrums illuminated equally and well. She was referred to Dr. E. W. Caldwell for roentgenograms of the sinuses and to Dr. John E. Weeks for examination of the eyes. The roentgenograms showed an absence of a frontal sinus on the right side, a fronto-ethmoidal cell taking its place; on the left side the frontal sinus was of moderate size and of normal appearance. The antrums were also normal. Dr. Weeks reported the eye examination as negative. Nasal examination remained negative. It was now noted for the first time that the patient had an edema of both upper lids, but no edema elsewhere. Trichinosis was suspected and on questioning the patient it was learned that she had recently eaten pork and that she had had a slight amount of muscular soreness in the region of the left deltoid insertion. She was sent to the Rockefeller Institute, where the diagnosis was confirmed and the following blood count reported: white blood cells, 14,000; eosinophils, 22 per cent. The case ran a mild, uneventful course terminating in recovery.

Case 2.—Mr. A. was referred to the nose and throat department of the Vanderbilt Clinic from the outpatient department of the Knapp Memorial Eye Hospital. He complained of pain in and about the left eye. As examination of the eyes at the hospital had been negative he was referred to the clinic as having a probable frontal sinusitis. Examination revealed an edema of both upper lids, more marked on the left than the right, but no edema elsewhere. Nasal examination was negative. His frontal sinuses illuminated equally and well as did also the antrums. A diagnosis of trichinosis was made and a differential blood count, made at once in the college laboratory, showed 20 per cent. eosinophils. This patient gave a history of having indulged freely in pork and also stated that he had had "rheumatism" in many of his long muscles. He was referred to the Presbyterian hospital but did not enter there and was consequently lost track of.

Case 3.—Miss L. B. B., aged 32, a settlement worker, was referred to me by Dr. T. H. Russell on June 28, 1915. Patient had been ill for about a week, suffering from nausea and vomiting, pain in the right shoulder and in right chest posteriorly. Physical examination had been negative except that a small area of dulness was found in the right chest posteriorly; no change in the breath sounds, no râles or friction rubs were heard. On the day I saw her she had complained of pain in the region of the left upper lid and left frontal sinus, and as she had a slight "cold in the head" it was thought well to eliminate the possibility of an acute frontal sinusitis. Examination showed edema of both upper lids and a moderate amount of puffiness of the face, but no edema elsewhere. There was no muscular tenderness. Examination of the nose and accessory sinuses was negative. She gave a history of having eaten pork frequently. A diagnosis of trichinosis was made and a blood count ordered. The count was as follows: white blood cells, 15,000; polymorphonuclears, 77 per cent.; lymphocytes, 16 per cent.; eosinophils, 6 per cent.; transitionals, 1 per cent. The next day she developed very severe muscular pains in both lower extremities and in the left wrist and left hand, and a moderate pericarditis. Vomiting persisted and the patient was extremely ill for the next week. Two more counts were made at intervals of three days each and showed an increase of eosinophils, first to 14 per cent. and later to 22 per cent. Her symptoms gradually subsided and she made a complete recovery.

The diagnosis in all three cases rested on (1) edema of the lids (and in Case 3 of the face also) with absence of edema elsewhere; (2) negative nasal findings referable to the accessory sinuses; (3) the history; (4) the eosinophilia. It will be noted that in all these the "presenting symptom," as Cabot so well terms it, was pain in the region of the eye and frontal sinus; in only one case (Case 3) was the so-called choleriform stage present.

41 West Eighty-Third Street.

Chloroform in the Treatment of Insolation.—Case 1.—Man, aged 37, was found in a state of unconsciousness from insolation. After two hours of futile effort to revive the patient, I concluded to try chloroform as an experiment. I gave it very lightly for five or ten minutes by inhalation, and rapid improvement in symptoms occurred. This led me to further experiment in the two cases following.

Case 2.—A robust, well-nourished boy, aged 4, after three hours of unconsciousness, was found with a temperature of 107, pulse above 200, stertorous respiration, profound stupor and complete relaxation. The patient was stripped of clothes and laid on a bed, and chloroform was administered cautiously by inhalation. No other treatment was given the first half hour. In twenty minutes the pulse had dropped to 160, the respiration was quieted, and in half an hour the pulse was 145, the temperature 105, respiration was greatly improved, tonicity of muscles was returning, and the child manifested some return of consciousness. From this time on, the ordinary treatment was given with uneventful recovery.

Case 3.—Man, aged 25, was overcome by heat while working in the hayfield in the afternoon. On arriving at 8 p. m., I found the patient in a profound stupor and complete relaxation, pulse 165, temperature 106.6. Except for the removal of some light clothes, chloroform cautiously given by inhalation was the only treatment in the first half hour. Results were similar and equal to those in Case 2, followed by uneventful recovery under the ordinary treatment.

George C. Hanson, M.D., Charlson, N. D.

New Instruments and Suggestions

A SIMPLE INSTRUMENT FOR THE INDIRECT TRANSFUSION OF BLOOD

Bertram M. Bernheim, M.D., Baltimore
Instructor in Clinical Surgery, Johns Hopkins University

Briefly, the apparatus consists of two needles, one of which is inserted into a vein of the donor, the other into a vein of the recipient, and a U-shaped tube, at the midpoint of which is a pocket into which a hollow revolving plug is fitted. This plug is open at one end so as to accommodate the nozzle of a record syringe (the plug may be made to fit any other form of syringe desired), but is closed at its other end, the point of exit being in one side so as to correspond to the openings of the two arms of the U into the central pocket. The distal ends of the arms, then, fit into the needles which have been placed in the donor's and the recipient's vessels. A circuit having been completed in this manner, blood is withdrawn by means of a syringe from the donor, and the plug is gently rotated for a half circle until its lateral opening faces the opening of that arm of the U leading to the recipient's vein, whereupon the syringe is emptied. Reverse rotation brings the plug's opening into apposition with the intake tube, whereupon the syringe is again filled only to be promptly emptied into the recipient by a half rotation of the plug similar to the first movement. In other words, the syringe draws up blood from an intake tube and empties it into an outgoing tube, the rotating plug acting as an intermediary between the two tubes.

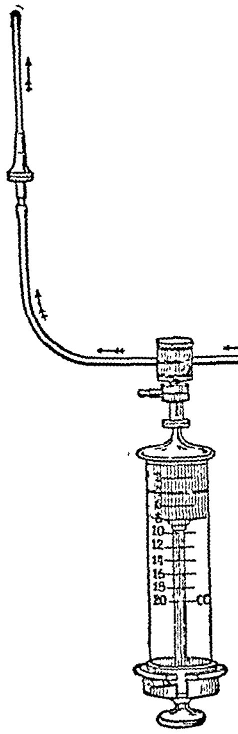

Fig. 1.—Instrument for indirect transfusion ready for use. Arrows indicate direction of blood current.

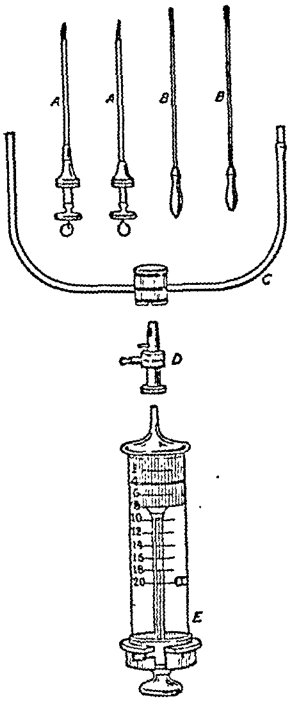

Fig. 2.—Instrument disconnected: *AA*, needles; *BB*, obturators; *C*, U tube; *D*, revolving plug; *E*, syringe.

A small metal ball attached to the plug facilitates its rotation, and another metal pin prevents its rotating more than a half circle by working in a specially constructed slot. Furthermore, the plug is ground into its pocket, and, though easily removable, fits so perfectly as to prevent entrance of air into the syringes. Worthy of note, too, is the fact that when the lateral opening of the plug is "set" for one arm of the U, the other arm is effectually blocked, thus preventing any leakage.

In this manner successive syringefuls of blood may be withdrawn from the donor and emptied into the recipient with accuracy, precision and rapidity. And inasmuch as no syringe should ever be refilled more than two or three times without cleansing, it is quite simple as well as advisable to wash a few cubic centimeters of salt solution into each arm of the U as each fresh syringeful is taken up. Thus clotting is avoided. Should, however, a clot arise or should it be necessary for any reason to discontinue the transfusion temporarily, the entire apparatus may be disconnected, washed out and held ready for continuing the operation.

The bore of the needles and tubes is 2 mm., and the arms of the U are separated from each other by 12 cm., a distance quite sufficient to permit of easy manipulation when applied to apposed arms of donor and recipient. It might be added, too, that in addition to being constructed to fit special needles, this U tube is also made to fit the two-pieced tube devised by me for direct transfusion (The Journal, April 6, 1912, p. 1007). This was done because occasionally it is impossible to see the desired veins, and incision is required. In such a contingency the two-pieced tube may be easier to work with than the needles. And there is no reason why, if one is in a great hurry, the intake tube should not be placed in the radial artery instead of a vein.

2313 Eutaw Place.

A NEW MUSEUM JAR FOR THE PRESERVATION OF EYE SPECIMENS

Henry Albert, M.D., Iowa City, Iowa

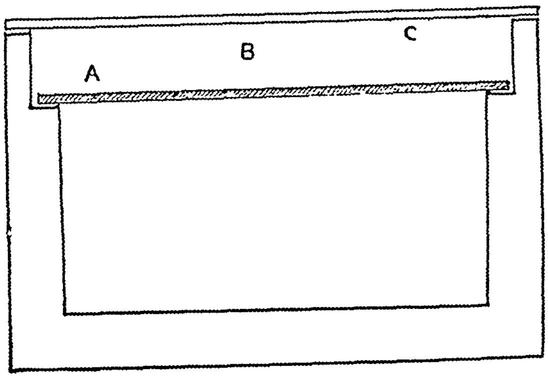
The difficulties encountered in the proper mounting of specimens of eyes in a permanent form have been so great that many persons who obtain eye specimens are deterred from mounting them because of the fact that a supposedly permanent preparation usually proves a disappointment in the course of a year or two.

There is room for much improvement in the present-day methods of mounting and labeling museum preparations of eyes.

The features desired in a museum jar are:

1. Ability to display well the structures desired.
2. Good appearance and convenience of handling specimen jar.
3. Permanency of the preparation.
4. Proper and permanent method of labeling the specimen.

Several of the museum jars for the preservation of eye specimens, now on the market, display the first two features. None of them, to the proper degree, exhibit the last two, especially when all of the desired features are considered.



Jar for the permanent preservation of eye specimens. *A*, inner cover of opaque white glass; *B*, space between two covers to be filled with cement; *C*, outer cover of transparent glass beneath which label is attached.

With the idea of remedying such defects, I have so modified one of the commonly used jars as to insure both permanency of the specimen and proper labeling, in connection with the other desirable features which the jar already possesses (see illustration). This is accomplished by a double cover which is, as usual, placed behind the specimen. The inner of the two covers is made of white glass to furnish the proper background for the specimen. The outer cover is made of transparent glass beneath which the label is placed—thus insuring the permanency of the label. Between the two covers is a space which is filled with the proper kind of sealing material. This entirely prevents evaporation of fluid from the jar and insures the permanency of the specimen. The distinct advantages of the jar here described, over the jars now on the market, are that it insures: (1) permanency of the preparation; (2) neatness and permanency of the label.

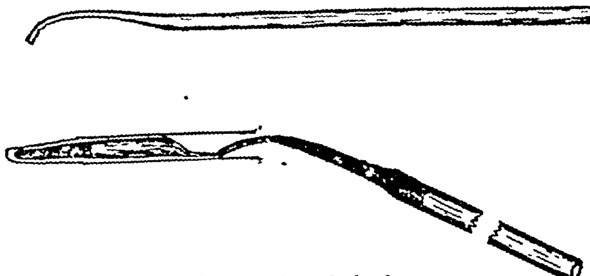
The jar here described is manufactured by F. A. Hardy & Co., Chicago.

Medical Laboratory Building.

A NEW PIPET

J. E. Huber, M.D., Peoria, Ill.

Some time ago I had difficulty in removing small quantities of separated serum from a small, narrow centrifuge tube. The usual method of capillary attraction with a fine-bore glass tubing pipet failed, owing to the fact that if I tipped the tube sufficiently for the pipet to act, the serum movement would cause the sediment to mix, defeating the object, which was separation of the serum. In a wide tube it is not difficult to raise the capillary point of the pipet higher than the finger end, high enough to increase the flow materially.



Pipet and method of use.

Narrow tubes are much more of a problem. My experience with Wright's pipets for blood collection gave me an idea which I have not seen mentioned. The end of the drawn out part of the pipet, a millimeter in diameter, is carefully flamed so that it curves about 45 degrees, say about one quarter-inch from the tip, as in the accompanying illustration. With such a pipet it is possible to withdraw fluids from watch crystals held on the flat, and from tubes which are too small to permit the use of a straight pipet. It is only necessary to have a clean pipet, and touch the curved end to the liquid, keeping the finger end lower than the curved end. Capillary action will fill the narrow tube beyond the distal curve, and the siphon action does the rest. Its action is instantaneous with aqueous liquids; with serum it is a little slower, but it will drain completely any kind of a tube, straight or curved.

It is simpler than the rubber nipple pipet, and is under better control, as the release of pressure on the nipple sometimes is great enough to cause currents that whirl up the sediment and spoil the experiment.

THE PAINLESS DRESSING

S. S. Gale, M.D., Roanoke, Va.

The dressing is yellow petrolatum with 10 per cent. boric acid incorporated in it. This boric acid ointment is prepared by the druggist and placed in a tin can. The regular petrolatum can of 1 to 5 pounds is an excellent container.

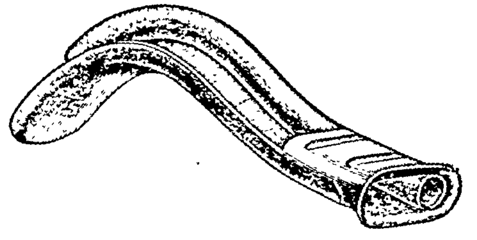
At each dressing the can containing the ointment is placed in a water bath and allowed to melt. This melting also resterilizes the ointment for each dressing. After the ointment has thoroughly melted it is poured into a large, flat, sterile pan. Pieces of gauze of various sizes and thickness, depending on the nature of the wound, are saturated with this melted ointment. After the wound has been sponged off, preferably with alcohol and normal saline, warm dressings are applied directly to the wound surface. These dressings are changed as often as is necessary, depending on the nature of the wound. When large areas are to be covered, it is usually best to have rolls of gauze about 8 inches broad and as many thicknesses as are necessary. These rolls are placed in the melted ointment and thoroughly saturated; then they are unfolded and applied directly to the wound. The greasy dressing can then be covered with plain gauze and held in place with a roller bandage.

This dressing does not dam back secretions, nor does it allow the granulations to embed themselves in the meshes of the gauze, and it can be removed absolutely without any pain. It will not dry out for several days. To my mind it is the ideal dressing in a large number of cases in which there is a large raw area to be covered.

A PHARYNGEAL TUBE COMBINING REBREATHING AND INSUFFLATION

Frank Wilcox Pinneo, M.D., Newark, N. J.

In all inhalation anesthesias the most frequent and important embarrassments to respiration are obstructions in the air way. Of all causes of obstruction the tongue falling back on the glottis is altogether the most common. As this fault in technic is within the control of the anesthetist and always removable, means to facilitate holding the tongue forward are practicable without the necessity of holding the jaw forward with the hand. There has been developed in insufflation an improved method over any kind of mask for administering ether, and pharyngeal insufflation has proved that the advantages in almost all kinds of cases may be secured without the necessity of intratracheal apparatus. When the nasal catheters are not used, but introduction by mouth is preferred, the combination of a rebreathing tube, to keep the tongue forward, and a tube for insufflation of the ether is a great convenience, and for this purpose the one shown in the illustration has been devised. It is a one piece metal blade with upturned sides to fit the contour of the tongue, having a channel for introduction of an oral catheter, 5 inches long; is curved from lips to pharynx, the mouth end being a flattened tube and adjustable for different sized patients. Its advantages are: 1. It provides for automatic holding of the tongue forward without other means. 2. It has not the objections of a closed tube, being an open blade with channels easily cleaned. 3. It can be used in patients of different sizes. 4. It has a channel for introduction of an oral catheter for pharyngeal insufflation, the catheter not being part of the pharyngeal tube. 5. The anesthetic may therefore be stopped while the blade remains in place. 6. It is efficient in holding the tongue forward without being so cumbersome as a tube like Connell's or a fenestrated frame like Lumbard's. 7. It is efficient for rebreathing, keeping the teeth and lips apart and the tongue forward. 8. It does not get clogged with mucus or blood.



Rebreathing tube combined with a tube for insufflation of ether.

199 Garside Street.

The Returns of Medical Practice.—For a livelihood, the practice of medicine brings in slow return, depending on location and opportunity. Success is laggard, as a rule, and even when emoluments balance expenditures, the profit in the practice of medicine is not considerable. The exceptional physician may grow well to do through fortunate investment, but outside of the larger cities, few get rich.—Isadore Dyer, M.D., *New Orleans Med. and Surg. Jour.*

Therapeutics

LEUKEMIA

Three papers on this generally fatal disease appear in the *California State Journal of Medicine*, September, 1915. The writers of these articles very practically present the treatment of leukemia which has shown the greatest success in prolonging a fatal termination.

Oliver (*loc. cit.*, p. 355) defines leukemia as "a malignant (idiopathic) hyperplasia affecting the leukocytic forming tissues, which results in an enormous increase in the production of white blood corpuscles." Only one type of white corpuscle is generally increased; the other types may be diminished. Occasionally more than one type of corpuscle is increased. The classification now accepted is that of Ehrlich, viz., the lymphatic and the myeloid, depending on the kind of cell that is increased in number. In lymphatic leukemia not only the lymph glands but also the spleen and other lymphoid tissue of the body may be affected, and even the bone-marrow. At any time during the course of the leukemia an acute infection may cause a rapid diminution in the numbers of leukocytes. Even slight infections in these cases of leukemia may cause death, or, if the patient recovers, the number of leukocytes rapidly again increases.

Boardman (*loc. cit.*, p. 348) has treated three cases of leukemia with benzene, and has also reviewed the literature since Korányi first suggested this treatment of leukemia, in 1912. Boardman comes to the conclusions that the benzene treatment of leukemia is the most successful yet offered; that the treatment is applicable to all forms of chronic leukemia; that when properly administered there is little danger from the treatment, but that the improvement is generally perhaps only temporary. In combination with the Roentgen-ray treatment, however, benzene treatment should be tried in all cases, except perhaps when there is nephritis.

BENZENE TREATMENT

Benzol is a trade name for benzene. It is used particularly in German literature. The benzol of commerce is impure and variable in composition. Selling[1] showed that the action of "benzol" is that of benzene. "Benzene, Medicinal," is described in New and Nonofficial Remedies, and Merck has a product on the market complying with this description.

There seems to be, as Boardman states, "abundant experimental and clinical proof that benzene acts on the leukoblastic tissues, causing a marked decrease in their functional activity in both normal and abnormal states."

During its administration benzene can cause headaches, dizziness, gastro-intestinal disturbances, and skin eruptions. It may cause too great a loss of leukocytes, hemorrhages, and nephritis, and, of course, it can cause death. The most frequent unpleasant symptoms from the therapeutic administration of benzene are gastric disturbances, which range in all degrees from simple irritation to loss of appetite, vomiting, hiccough, etc. This action on the stomach can generally be prevented by combining the benzene with olive oil and giving it in gelatine capsules during a meal. If in spite of such a method of administration the benzene tends to disturb the stomach, the capsules may be coated with phenyl salicylate, which will generally prevent their solution until they reach the intestines, where the alkalies will dissolve and break up the salicylate. More or less persistent headache and dizziness and kidney and bladder irritability should be danger signals, and heeded by withdrawal of the drug. It should also be noted that the action of benzene persists for some time after the patient ceases to take it; therefore too great care cannot be taken in watching the results of its administration. Not only must unpleasant symptoms be noted and good judgment used as to whether or not the drug should be continued, but the blood must be repeatedly counted, and when the white corpuscles are reduced to 20,000 the treatment should be immediately discontinued. The occurrence of anemia, which is occasionally produced, should also be the signal for discontinuance.

Boardman and other clinicians, notably Barker and Billings, caution against the administration of benzene while the patient is ambulatory. A patient with leukemia under the administration of benzene should certainly be at rest, and perhaps best in a hospital. The drug seems to be equally beneficial in chronic myelogenous and chronic lymphatic leukemia.

The method of its administration, as mapped out by von Korányi, and found by Boardman to be the most satisfactory, is to give it in gelatin capsules prepared just before the administration, each capsule to contain 0.50 gm. of benzene, with an equal amount of olive oil, these capsules to be swallowed during the meal. On the first day four capsules, representing 2 gm. of the benzene, should be given; on the second day 3 gm. or six capsules; on the third day 4 gm., eight capsules; on the fourth day, and to continue at this dose, 5 gm., ten capsules. This latter dose should not be exceeded, and should be reduced if the symptoms show undesired action. The drug should be stopped, as above stated, as soon as the white corpuscles have become as low as 20,000 per cubic millimeter.

ROENTGEN-RAY TREATMENT

Ruggles (*loc. cit.*, p. 355) briefly describes this treatment of leukemia. He finds that since Schultz, in 1901, and Pusey, in 1902, and Senn, in 1903, reported their first cases of leukemia treated with Roentgen ray, thousands have been so treated. The usual result of such treatment has been a more or less rapid diminution of the white count and an improvement in the general condition. There are records of patients so treated being still alive after five years, and some of them apparently well. Recurrences, however, generally take place. Ruggles finds the contraindications to Roentgen-ray treatment of leukemia to be acute forms and the coincident condition of profound anemia, and cachexia or fever. The primary effect of the treatment is that "in ten to fourteen days the lymphocytes, myelocytes, myeloblasts, and even polynuclears show swelling of the nuclei and a fragmentation of the chromatin." Later the protoplasm of the cells becomes clear or vacuolated and then the cells disappear. After a prolonged course of roentgenation the myeloid cells completely disappear from the lymph nodes and the spleen, the latter becoming "a fibroid mass containing scattered lymphoid cells."

The best results in leukemia are obtained by exposing both the long bones and the spleen to the Roentgen ray.

---

[1] Selling: Bull. Johns Hopkins Hosp., 1910, xxi.

To sum up, the best treatment of leukemia, as far as our present knowledge goes, is the combined treatment of Roentgen ray and benzene. Benzene is a dangerous drug, and its action must be carefully watched. The Roentgen ray is a very potent force and may do harm, but the disease has always been, with unexplained intermittencies, almost invariably fatal; hence radical measures are excusable in its treatment. The old treatment of arsenic in enormous doses doubtless caused more deaths than can be attributed to benzene or to any late secondary action of the Roentgen ray.

INFANTILE SCURVY

This nutritional disturbance is becoming less frequent with the better understanding of what constitutes the proper artificial food for babes and young children.

Most proprietary foods, many cereal gruels, and overpasteurized or sterilized milks are deficient in one or more elements necessary for health and nutrition. Rarely even a mother's milk may be deficient in such elements as to allow scurvy in her nursing child.

The importance of the various amino-acids for the growth and nutrition has been shown by Osborne and Mendel, and their work has clarified many of the empiricisms while furnishing many surprises in food values. Suffice it to say that some of the amino-acids are vitally important for nutrition, and if they are absent a child will not grow normally.

In scurvy the child seems to be short of alkaline salts and the food must have been insufficiently supplied with these; or, in the case of cow's milk, too long boiling or sterilizing has so changed the normally contained alkalies as to make them unavailable for nutrition. Supplying these alkaline salts to the child generally cures the condition quickly. These salts are readily offered by the juice of fresh oranges or grapes, or by a potato soup.

This condition of infantile scurvy is referred to because, as it occurs less and less frequently, it is often overlooked or confounded with rheumatism. Infantile scurvy most frequently occurs after 6 months of age and before the age of more general feeding, that is, while the child's diet is still limited to one or two articles of food. On the other hand, rheumatic fever is very rare in children during the first eighteen months of life.

The symptoms of infantile scurvy are joint pains, muscle soreness, crying on being handled, not much fever, loss of appetite principally because the mouth and gums are sore, bleeding from the gums or slight hemorrhages into the mucous membrane of the mouth and gums. If the child has been long sick and long refusing food, he is pale; and he is anemic if there has been much bleeding. If the condition is early recognized, the child may not be ill nourished. The Roentgen ray will often show more or less swelling or infiltration of the bones, and a chest examination, according to Hess,[1] will show "an enlargement of the heart, and more especially of the right side."

Besides the oranges or potato food, the child should be given 1 drop of the tincture of ferric chlorid three or four times a day. The mother or nurse may add this drop of the tincture to each feeding of orange juice. The amount of orange juice given should be that from one or two ordinary sized oranges per day. If diarrhea is caused, grape juice or potato soup may be substituted. Diarrhea should be prevented, as it makes the prognosis less favorable.

The joints may be kept warm with cotton, much as is done in rheumatism. A proper food for the child should be selected, and he should be rolled in a comfortable carriage into the fresh air. He should not be handled more than is absolutely necessary until he has recovered from his soreness and joint pains. The gums may be gently massaged by the mother or nurse. A little cold water frequently given the child is very acceptable in relieving the burning and irritation of the mouth. If there is bleeding, swabbing with boric acid solution and touching oozing spots with suprarenal solutions is advisable. If there are large bleeding areas in the mouth, swabbing with hydrogen peroxid solution is efficient. It may also be well to give the child an extra amount of lime as presented by the glycerophosphate of lime in 0.05 gm. powder, three times a day.

New and Nonofficial Remedies

THE FOLLOWING ADDITIONAL ARTICLE HAS BEEN ACCEPTED BY THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION. ITS ACCEPTANCE HAS BEEN BASED LARGELY ON EVIDENCE SUPPLIED BY THE MANUFACTURER OR HIS AGENT AND IN PART ON INVESTIGATION MADE BY OR UNDER THE DIRECTION OF THE COUNCIL. CRITICISMS AND CORRECTIONS ARE ASKED FOR TO AID IN THE REVISION OF THE MATTER BEFORE PUBLICATION IN THE BOOK "NEW AND NONOFFICIAL REMEDIES."

THE COUNCIL DESIRES PHYSICIANS TO UNDERSTAND THAT THE ACCEPTANCE OF AN ARTICLE DOES NOT NECESSARILY MEAN A RECOMMENDATION, BUT THAT, SO FAR AS KNOWN, IT COMPLIES WITH THE RULES ADOPTED BY THE COUNCIL.

W. A. PUCKNER, SECRETARY.

RADIO-REM, OUTFIT NO. 4.—An apparatus designed for the production of radioactive drinking water by the action of radium sulphate. It imparts about 1.8 microcurie (5,000 Mache units) to 500 Cc. water daily. (The exact efficiency is stated and guaranteed at the time of sale.)

Actions, Uses and Dosage.—See general article on radium, New and Nonofficial Remedies, 1915, p. 262.

Radium Therapy Corporation, New York (Schieffelin and Co., New York). No U. S. patents or trade-marks.

Radio-Rem Outfit No. 4 consists of two wide-mouthed glass-stoppered bottles of about 250 Cc. capacity, each containing a fired, porous clay (terra cotta) plate, stated to contain radium sulphate. While each plate is designed to impart about 0.95 microcurie (2,500 Mache units) to the water which fills the bottle in twenty-four hours, the efficiency of each tablet is stated at the time of sale and the manufacturers agree to replace the tablets and to pay for the test, if examination by the U. S. Bureau of Standards shows them to be deficient.

A test made for the Council demonstrated that during the impregnation of the water with radium emanation, no radium is dissolved in the water.

Praises for New Hanover County, N. C.—In a recent issue of the *Public Health Reports*, the United States Public Health Service calls attention to the sanitary progress that is being made in the city of Wilmington and the county of New Hanover. During 1914, 1,856 flushed closets were installed in Wilmington alone; in Cape Fear township every home has a water closet and in Masonboro township, the same condition is found. The actual field work in this county has been done by sanitary policemen and through persuasion rather than by court measures. The Wilmington City Council has voted to make available the sum of $50,000 on loan for the exclusive purpose of changing privies to flushed closets.

THE IMPROVEMENT OF THE PUBLIC HEALTH

Anniversary and other formal public addresses before scientific audiences are likely to be reminiscent in character, reviewing the achievements of the past and sounding the praises of those who are responsible for them. An uncommon and distinctly meritorious feature in the recent address of Prof. W. T. Sedgwick, as president of the American Public Health Association, is the frank and vigorous presentation, not only of the record of American progress in public health work but also of some of its shortcomings and failures.[1] A few of the latter deserve to be brought to the attention of a larger medical audience because they involve aspects of our daily life which are of primary concern to the physician and regarding which he may properly be expected to assume an attitude of vigorous advocacy. Usually it takes considerably more courage and initiative to condemn inertia or indifference in public authorities than to commend the successes for which they are responsible.

Among the much-needed sanitary improvements which we have failed thus far to achieve in proper degree Sedgwick classes the sewage disposal systems. The public water supplies are today receiving an increasing amount of intelligent consideration from health authorities; but there is too little care devoted to the problem of human excretory waste. Public comfort stations and comparable public sanitary conveniences are among the rarities in American cities and towns. This almost universal lack, in this country, concerns one of the very elements of public health.

Sedgwick maintains that typhoid fever has not yet been reduced as far as it should have been in America. He also is frankly critical regarding the situation in respect to American infant mortality. "We have as yet," he remarks, "and in spite of ample knowledge, failed to make our American milk supplies what they should be. This is partly because we have been too timid to insist that good milk not only costs more to make but is worth more for food, and must therefore be paid for, and partly because we have not yet taught the public as we should that the only safe milk is cooked milk, and for infants, milk that is pasteurized—preferably in the final container."

Among other items which receive the charge of "conspicuous failure" are present rural and industrial hygiene and sanitation, and the problems of alcoholism and venereal disease. We are reminded that in many cities the streets—the playgrounds of the poor—are disgracefully dirty, and that we have not done all we might for the prevention of blindness, of tuberculosis or of cancer. Our vital statistics are not yet either complete or trustworthy; our health boards are too often loaded up with political refugees, political doctors, and ignorant or incompetent laymen. Our health officers are frequently untrained, ill-paid, or only part-time employees of a no-time board. It is not denied that great progress has been witnessed in many of these fields of public health endeavor. Sedgwick's attitude is rather that of a scientist impatient at the slowness with which modern contributions to knowledge have been put to use in public practices.

Sedgwick makes a further timely comment in directing attention to the neglect of what he terms preventive personal hygiene in contrast with preventive medicine and preventive sanitation. By this he means the study and care of the individual in those aspects of correct living to which we recently referred.[2] It may not be comforting to be told that even our best medical schools pay but scant attention to the manifold aspects of preventive hygiene and sanitation and that "the best teaching of today is to be found, not in the text-books or the schools, but in the leaflets issued and distributed by certain leading boards of health and life insurance companies." Criticism becomes a reproach only when it is never heeded and the better paths to which it points are never followed.

EFFICIENCY OF THE BODY AS A MACHINE

Ever since Count Rumford first suggested that the muscular work of two horses produced enough heat to boil water, speculation has been rife as to how much heat man loses during work and how efficient the human body is as a machine. The relationship between the energy consumption and the output of work has been extensively studied with various methods and machines. Dumas and Boussingalt,[3] by determining that a man used 300 gm. of carbon in climbing Mont Blanc, computed the efficiency of the body as 33 per cent. Frick[4] found that under the best conditions isolated muscle has an efficiency of 25 per cent. Gautier estimated that a working diet is 1,780 calories in excess of a resting diet, and that a man produces 270,000 kilogrammeters of work per day, which is equal to 588 calories. But of the 270,000 kilogrammeters, 100,000 are lost in the different movements of the body and "in the friction of the machine," so that the useful work is 150,000 kilogrammeters, or 352 calories. Therefore, of the 1,780 calories but 352 are transformed into work, giving a net efficiency of 20 per cent. Smith[5] found that, of the total heat incidental to muscular work, only one fifth was used in the production of mechanical work.

[4] *Frick: Arch. f. d. ges. Physiol.* (Pflüger's), 1878, xvi, 58.

There are notable inaccuracies, however, in each of these methods; hence the careful studies and the improved methods used by Benedict and Cathcart[6] in determining the efficiency of the body are especially valuable. These investigators used a bicycle with an accurately calibrated electric brake. The amount of oxygen consumed and the carbon dioxid produced by a man riding this bicycle ergometer was determined with a new form of respiration apparatus. Benedict and Cathcart thus determined the amount of heat that was eliminated per minute and the nature of the materials that were burned in producing this heat. All tests were performed twelve hours after the last meal, so that the food materials used were those stored in the body. By computing the relationship between the heat equivalent of the external muscular work as measured by the ergometer and the total heat output, they found that the net efficiency varied from 9 to 24 per cent., depending on the various speeds and loads that were placed on the bicycle rider. These differences are easily explained on comparison with a steam engine. A certain amount of steam is used in keeping up heat when the engine is not working at all. Slow revolutions and also too rapid revolutions of the fly wheel are less efficient in the production of work. In short, there seems to be a certain rate of speed for each engine at which it is most efficient. So it is with man in work production. Benedict and Cathcart found the average net efficiency of a professional cyclist and of four untrained men to be about 21 per cent. for each person. They found that the output of heat was constant per ten revolutions of the bicycle pedals, but that the increase in effective muscular work was not constant; there was a falling off as the higher rates are reached. The optimum efficiency was at 70 revolutions per minute. One objection to the accuracy of these results is that the cutaneous respiration is not considered, but this is a minor factor and would influence the final result but little.

Chauveau first found that during muscular work there is an excessive combustion of carbohydrates, so that in the subsequent period the catabolism is that of a body deficient in glycogen. Benedict and Cathcart have confirmed this and have demonstrated that the more severe the muscular activity, the heavier the draft on the carbohydrate material in the body. On the cessation of work the so-called "specific working catabolism" disappears, and for a time a much lower portion of carbohydrates is burned for the total energy output than during a usual resting period. Chauveau has also contended that when the supply of glycogen is depleted, fat may be converted into glycogen. According to Chauveau, 30 per cent. more energy per unit of work is liberated than when carbohydrate is burned, since heat which cannot be otherwise utilized is set free during the conversion of fat to glycogen. The transformation of fat into glycogen, however, lacks conclusive proof, and Benedict and Cathcart have not observed the additional heat loss even in work experiments so severe that fatigue resulted.

This question of body efficiency is closely linked with athletic training, a subject about which we are still poorly informed. From this work it would seem that training influences metabolism but little and that diets are not so prominent a factor as we have assumed.

RADIUM AS A FERTILIZER

Discoveries, so long as they are novel, naturally excite expectant optimism as to their application. This is the stage at which honest but undiscriminating enthusiasm and deliberate fakery both flourish. Radium, the possibilities and limitations of which are still undefined, is an instance in point. Time and experience are needed to reduce to rational limits the many claims made for it.

One of the uses suggested for radium is the stimulation of plant growth. Various experimenters have investigated the effect of radium emanation on the growth of plants under laboratory conditions. Gager, Fabre and Stocklasa have each reported stimulation of the growth of plants or the germinating activity of seeds under the influence of an optimum strength of radium, while a greater strength retarded growth.

The results of these laboratory experiments aroused interest in the possibility of using radium as a soil fertilizer under practical agricultural conditions. H. H. Rusby, professor of materia medica in the College of Pharmacy of Columbia University, has made experiments in this direction. He arranged with the Standard Chemical Company of Pittsburgh to use as a fertilizer the powdered residue carnotite ore left after the extraction of all the radium possible. This residue, or ore tailings, is said to contain about 2 or 3 mg. of radium to the ton. It was applied, mixed with fertilizer, on various contiguous plots in proportions of about 25, 50, 100 and 200 pounds to the acre, respectively. Control plots were treated in the same way except that they did not receive the radioactive mixture.

---

[5] Smith: Phil. Tr., 1859, cxlix, 681.

[6] Benedict and Cathcart: Muscular Work, Publication 187, Carnegie Institution of Washington.

Rusby's report[1] is published in the house organ of the Standard Chemical Company. It describes in glowing terms quite remarkable results, which, if they could be accepted, *would mark a new era in agriculture*. Nearly all field crops showed an increased yield. Many garden vegetables in treated plots attained a larger size than those in untreated plots. Mere proximity to treated plots seemed to affect favorably the size of vegetables in untreated plots. Rusby also believes that the quality and palatability of vegetables and the size and brilliancy of flowers were improved by the influence of the radium ore mixture.

These results are not confirmed by field tests recently made at the University of Illinois. C. G. Hopkins, professor of agronomy, and W. H. Sachs,[2] chief in agronomy and chemistry at the Agricultural Experiment Station, report field tests of radium fertilizer made at the University of Illinois during 1913 and 1914.

In these tests the radium was used at three rates of application, 0.01 mg., 0.1 mg. and 1 mg. of radium per acre, costing, respectively, $1, $10 and $100 per acre. On one series of plots the radium was applied in the form of radium barium chlorid solution diluted with distilled water. The check plots received the same quantity of distilled water without radium. Another series of plots received solid radium barium sulphates, thoroughly mixed and pulverized with dry soil from the field. The control plot received the same weight of soil without the radium. Hopkins and Sachs explain that the amount of radioactive substance applied in these tests was made small in order to avoid any appreciable effect from the substance other than that due to radioactivity. Some effects might conceivably be obtained from the application of 100 or 200 pounds of mineral salts per acre. In the heaviest applications the amount was less than 5 pounds of total salts per acre.

Corn was grown on the land in 1913 and soy beans in 1914. The work of the two years comprised 144 tests with corn and 240 tests with soy beans.[3] In all these tests the average variation from the controls was so slight and so evenly distributed, for and against, as to compel the conclusion that radium, at any of the rates applied, had produced no effect on the crop yields either the first or the second season.

It will be observed that, whereas the University of Illinois investigators avoided applying any large bulk of salts, Rusby applied his radium in the form of refuse carnotite ore. Of this he used from 25 to 200 pounds per acre, as against the small amount (less than 5 pounds per acre) employed at the University of Illinois. That is, of course, Rusby applied practically from 25 to 200 pounds of the constituents of carnotite (a hydrated vanadate of uranium and potassium) along with the radium. The amount of radium with which he treated the soil per acre, taking his own highest estimate of 3 mg. to the ton of ore tailings, must have been approximately from 0.3 mg. to 0.04 mg. as against the 1 mg., and 0.1 mg. and 0.01 mg. used at the University of Illinois.

A *reductio ad absurdum* of the radium fertilizer theory is given by R. R. Ramsey,[4] associate professor of physics in Indiana University. It is well known that radium is universally distributed, being present in most substances, however, only in minute traces. Taking Rutherford's average value for the amount of radium in the crust of the earth, Ramsey figures that the amount of radium element in the upper 5 inches of an acre of soil is 1 mg. Thus the maximum amount of radium used by Hopkins and Sachs (1 mg.) merely doubled the amount of radium element in the upper soil; the maximum amount used by Rusby increased the amount of radium element by only about one third. The amount of radium emanation which issues from an acre of soil, however, is not confined to the emanation from the radium element in its superficial 5-inch layer; it is from 50 to 100 times as much. Hopkins and Sachs increased the amount of radium emanation in the soil by only about 1 or 2 per cent.; Rusby increased it by only a fractional percentage.

As remarked earlier, experiments indicate that it is possible to increase vegetable growth, under laboratory conditions, by the application of radium. It may be that eventually some means will be found by which radium can be utilized in practical agriculture. At present, however, the best evidence we have does not encourage us to regard this as an immediate possibility.

GAS DIFFUSION IN THE LUNGS

With increasing altitudes the pressure of the air is reduced, and the oxygen tension becomes lower and lower. At a height of about 15,000 feet the barometric pressure is little over half an atmosphere, and the oxygen tension therefore only about 11 per cent. of an atmosphere. The presence of man at any considerable altitude necessitates an adjustment on his part so that the persistent undiminished oxygen requirement of the organism can be satisfied under the enforced changes of atmospheric conditions. Otherwise serious symptoms, which go under the designation of oxygen starvation, may arise. They doubtless play some part in the malady familiarly known as mountain sickness.

One of the adaptations to the barometric conditions prevailing at considerable heights is an increased pulmonary ventilation. There is an augmentation in both depth and frequency of respiration. The increase in pulmonary ventilation diminishes the alveolar carbon dioxid tension, increases the oxygen tension, and improves diffusion. Another important means of rapid adaptation is associated with changes in the circulation. A deficient passage of oxygen from the lungs to the blood may, so far as heart and tissues are concerned, be accommodated for by increasing the rapidity of the blood flow. This is effected by a quickened pulse rate. Such responses are due solely to the low tension of the oxygen, as the recent experiments in the pneumatic cabinet at the Finsen Institute in Copenhagen have demonstrated.[1] Again, there may be an increased quantity of hemoglobin or of red corpuscles. If this response occurs, the necessary amount of oxygen can be transported with a slower rate of circulation, and the arterial oxygen tension can be raised.

[4] Ramsey, R. R.: Radium Fertilizer, Science, Aug. 13, 1915, p. 219.

Some years ago, Haldane and his collaborators arrived at the conclusion that, even when these facilitating adjustments and adaptations are taken into account, as soon as any considerable altitude is reached the necessary supply of oxygen cannot be furnished through the lungs to the blood satisfactorily by the mere process of physical diffusion of the gas. The expedition of the Duc d'Abruzzi in the Himalayas, in which a height of 24,600 feet, corresponding to a barometric pressure of 312 mm., was attained, has been recited as a striking example of the insufficiency of the simple diffusion theory. The problem concerns the forces by which oxygen is transported from the alveolar air into the blood. If the tension of oxygen in the blood is under certain circumstances higher than that of the alveolar air, there can be no doubt that forces other than diffusion must come into play. Haldane and his collaborators have maintained that this is, in fact, the case. The Anglo-American expedition of Douglas, Haldane, Henderson and Schneider to Pike's Peak in 1912[2] furnished further carefully selected observations which have been interpreted in favor of the newer hypothesis that the acclimatization at considerable altitudes is accomplished by an increased arterial oxygen tension due to active secretion of oxygen through the alveolar epithelium.[3]

Dr. Marie Krogh[4] of the University of Copenhagen has taken exception to this widely quoted hypothesis that simple diffusion of gases through the lungs of man is insufficient to explain intakes of oxygen measured under the most adverse conditions, and especially during muscular work at low oxygen pressures. On the contrary, it is maintained, as the result of the newest investigations, that diffusion alone will account for the gas exchange between the alveolar air and blood in all cases which have been examined in sufficient detail, both at low oxygen tension and during the heaviest muscular work. According to Dr. Krogh, during work at low oxygen pressures, it will as a rule be diffusion through the lungs which sets the limit for the intake of oxygen; during work at normal atmospheric pressures, the heart will probably in most cases be the limiting factor.

There are other newer results respecting the combustion processes in the lungs which harmonize well with these conceptions.[5] The discovery of the adequacy of simple physical processes to account for physiologic functions is always a source of satisfaction. The critical studies of Dr. Krogh make it seem unnecessary to assume any cellular activity on the part of the alveolar wall, either in the form of a direct secretion of oxygen, or in the nature of a combustion of intermediate metabolites supposed to increase the mean oxygen tension difference.

THE CAUSE OF RAT-BITE FEVER

It sometimes happens that a carefully formulated description of an unfamiliar group of symptoms serves to arouse sufficient consideration to bring to light other similar or closely related instances. Cases grow in number, and as medical attention is focused on them, a condition which was infrequently recognized or diagnosed may lose its rarity and enter into the group of less exceptional diseases.

With these thoughts in mind we refer to Crohn's recent contribution to the subject of rat-bite fever,[6] known in some of the foreign tongues as Rattenbiss-Krankheit or sokodu. This disease, best known in Japan, where it is recognized by the medical profession, occurs among the classes liable to be bitten by rats. The symptoms are incident to a bite and are followed after a variable incubation period by a single paroxysm or by regularly recurring paroxysms of chills, fever and sweats, lasting a few days, and associated with the occurrence of a local or diffuse bluish-red exanthem. The disease is often characterized by marked nervous symptoms. The course of the malady is signalized by progressive emaciation and weakness; the duration is variable, often very prolonged. Fatal cases are not infrequent.

From a study of about fifty cases reported in the world's literature, some of it dating back several decades, along with personal experience at the Mount Sinai Hospital, New York, Crohn has speculated on the nature of rat-bite fever as a disease. He notes that in the nature of its course it resembles most clearly relapsing fever, the febris recurrens of the Asiatics and Europeans. The diseases resemble each other in the intermittency of the symptoms; the incubation period in both is variable. In its favorable reaction to salvarsan the disease has a common factor with both syphilis and relapsing fever, but more particularly with the former. The finding of a spirochete as the cause of both the latter diseases suggests this as the etiologic factor in this malady. In the prominence of the nervous symptoms and the postfebrile paralyses, rat-bite fever recalls relapsing fever. The one reported postmortem examination in this disease revealed a serous meningitis, with increase of cerebrospinal fluid. The irregular paraplegias and atrophies recall the tabetic lesions of syphilis.

[5] Evans, C. L., and Starling, E. H.: Jour. Physiol., 1913, xlvi, 413. Henriques, V.: Biochem. Ztschr., 1913, lvi, 230.

[6] Crohn, B. B.: Rat-Bite Fever, Arch. Int. Med., June, 1915, p. 1014.

Many authors have indicated a belief in one of the species of protozoa as the etiologic factor, but with the exception of the statements of Ogata, whose work has unfortunately not been confirmed, such parasites have not been observed. Many of the symptoms of the malady might, in Crohn's opinion, be the result of a powerful toxin elaborated at the site of the wound and transmitted along the regional nerve paths to the central nervous system, in a manner similar to the propagation of the toxin of tetanus. The point in favor of a spirochete as the causative agent is the similarity of the disease to relapsing fever and syphilis, as regards both the marked nerve symptoms and the apparent curability by salvarsan. In favor of a protozoan cause is the alternation of the paroxysms with afebrile periods, recalling the effects of the malarial plasmodia, though this occurs also in spirochetal diseases.

Now that attention has been turned more prominently to the possibilities involved, new cases will undoubtedly be brought to light in greater number. We shall then perhaps be in a position to ascertain conclusively whether or not the disease is actually caused by living parasites, a conclusion to which much of the evidence presented strongly points.

Current Comment

THE COMPLEMENT-FIXATION REACTION IN TUBERCULOSIS

The presence in the serum of tuberculosis patients of a substance which is capable of binding complement in the presence of suitable antigen has been repeatedly demonstrated. Why this reaction has not come into more general use as an aid in the diagnosis and prognosis of tuberculosis is not apparent. Recent French literature contains observations on the diagnostic importance of this reaction. Besredka and Manoukhine[1] report the results of complement-fixation experiments in guinea-pigs, rabbits and human beings, using as antigen a tuberculin prepared from egg-broth cultures of tubercle bacilli. The test was positive in guinea-pigs after the fourth day of infection, and remained so with fluctuations until shortly before death, when it became negative. In man these observers found the reaction uniformly positive in the early stages of tuberculosis and in a majority of cases in the second stage. They observed partial or negative results in the third stage and regarded a negative reaction in advanced tuberculosis as a sign of approaching death. Debains and Jupille[2] report observations on a series of 600 individuals, including patients in all stages of tuberculosis, patients having various other diseases but no signs of tuberculosis, and apparently normal persons. Some of the latter gave feebly positive reactions. Also patients with a strongly positive Wassermann gave a positive reaction with tuberculous antigen, owing, it is suggested, to lipoids derived from the egg constituents of the medium which react with syphilitic serum in a manner similar to tissue-extract antigen. In advanced cases of pulmonary tuberculosis with cavitation and cachexia feeble or negative reactions were often obtained. In cases of tuberculous pleurisy with effusion negative reactions were frequent. These are explained on the supposition that in advanced tuberculous infections the antibodies in the serum have already been bound or neutralized by substances produced by the large numbers of bacilli present. Experiments with rabbits indicate that the complement-fixing activity runs parallel with the resistance of the animals to infection. If the same conditions obtain in human cases, the test would give valuable information to the clinician regarding the course of the disease. It would seem, from the evidence accumulated by workers in this field, that the complement-fixing reaction can be used with advantage in the diagnosis and prognosis of tuberculosis. The procedure certainly merits trial in hospitals and institutions dealing with tuberculous patients.

HEREDITY IN TWIN BIRTHS

In no field of study is the possession of accurate statistics more necessary than in problems of heredity. An interesting problem concerns the question of the likeness of animals and their offspring with respect to birth as singles, twins, or triplets. Heape,[3] in an analysis of the English statistics available, says that there is reason to believe that twin lambs produce more twins than single lambs, and that the influence of heredity is brought to bear. Rietz and Roberts[4] have taken up the question as determined by the statistics available in this country. In the classes of sheep studied in this instance—registered Shropshire sheep—they found that in general the twin parents give a larger percentage of twins among offsprings than do parents born as singles. They call attention to the fact that as it requires large numbers to establish the significance of the difference found, and it would not be surprising if within a flock of fair size—one hundred—one may in some cases get even a larger percentage of twins from single parents than from twin parents; but such fluctuations would not occur in the large majority of cases. What the significance of these results are for the human being can be determined only by a similar study of heredity in twin births.

EDIBLE SNAILS

To most Americans the idea of using snails in the diet will not awaken gastronomic enthusiasm; but there are people in various parts of the world to whom the suggestion of the use of other mollusks, such as oysters and clams, would be repugnant. It is not necessary to go back to the days of the elder Pliny for evidence that edible snails have had a place on the menus of many countries. It is stated that during our own oyster season, from September to April, more than 200 million snails are disposed of in Paris alone. The daily consumption of "escargots" in the French capital has been estimated at 50 tons when trade is at its best. In the belief that the American people can be educated to see the true worth of the edible snail, which might be grown with profit in the United States, a government expert has collected some facts bearing on their use.[1] The European war has added a further interest to the possibility of snail culture. Comparatively few Americans have ever tasted snails, know of their preparation as food, or even consider them a fit article of diet. Among the foreigners in our population, snails have a limited sale. Those sold in the fish markets of our larger cities have practically all been imported from France. Abroad, snails are by no means regarded in any sense as a national dish. They are included in the dietary much as is the oyster in this country, as a table luxury or delicacy. In respect to composition, the two groups of mollusks furnish about the same yield of nutrients. In Europe, snails are raised commercially under an intensive system of culture in many places in snaileries. Rust[1] believes that although snail culture may not be very profitable in Europe, where economic conditions are different, in that the food for the animals must be grown and supplied to them regularly and everything done with much labor on restricted areas of land, in the United States snail farming might, with judicious publicity, and in time, become profitable. Whether or not it is advantageous, from the standpoint of nutrition, to attempt to introduce a new food to the American table is a question of individual preference. Almost every one, Rust writes, who has ever eaten well-prepared snails, admits their gastronomic worth, from the points both of nutritive value and of flavor, and there are many states where they could be grown and kept fresh until used, and where they would prove a very welcome addition to the somewhat limited menu of the locality. In the Mississippi Valley, for instance, where conditions for their cultivation are almost ideal, they could be grown at practically no cost (either in money, time or labor), and might be used to a great extent in place of oysters, which they greatly resemble in flavor when properly prepared. Such a practice would be advantageous, for the snail is possibly preferable as an article of human consumption. It is cleaner, feeding daintily, as it does, only on the cleanest of vegetable tissues, while oysters, not being able to move about in search of food, must take what comes to them in the water, are sometimes fattened in water impregnated with bacteria-laden sewage, and thus, occasionally, act as carriers of typhoid and other diseases. At any rate, we can be prepared to receive the suggestion of the addition of snails to the American menu without the revulsion of feeling which it awakens in many at present.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

CALIFORNIA

Fresno Gets State Society Meeting.—The Council has decided that the 1916 meeting of the Medical Society of the State of California is to be held in Fresno in April.

Personal.—Fire in Caruthers, September 10, destroyed the office of Dr. George A. Meracle.——Dr. Lyle G. McNeile has been appointed deputy health commissioner of Los Angeles.

State Board Changes.—On September 2 Governor Johnson appointed Dr. Wilbur A. Sawyer, Berkeley, a member of the State Board of Health to succeed Dr. Donald H. Currie, Sacramento, the secretary of the board, resigned, and Dr. Robert A. Peers, Colfax, to succeed Dr. James H. Parkinson, Sacramento, term expired.——At a meeting of the Board, September 4, Dr. Sawyer was elected secretary.

State University Happenings.—Dr. James Craig Neel, San Francisco, has been appointed instructor in obstetrics and gynecology (on an academic basis); Dr. William Boericke has been appointed clinical professor of homeopathic materia medica, and Dr. Sanford B. Hooker and Carl L. A. Schmidt have been appointed research assistants in pathology in the University of California to undertake researches as to typhoid fever and in problems of biologic specificity, provided for by the Edith J. Claypole Memorial Research fund in pathology and George Williams Hooper Foundation for Medical Research.

Ordinance Regarding Diphtheria Carriers.—Among the cities in California which have ordinances providing for the isolation of diphtheria carriers are San Francisco and Berkeley, in both of which places opposition has arisen to the enforcement of the ordinance. In San Francisco an attempt was made in the Board of Supervisors to repeal the ordinance, and in Berkeley Assemblyman George Gelder has threatened to appeal to the courts to prevent the enforcement of the isolation ordinance. A number of his children had been affected by the law, being excluded from the schools on account of the discovery by the school inspectors that they were diphtheria carriers. Assemblyman Gelder, it is said, has been opposed to a number of health regulations, among them the laws in regard to vaccination against smallpox. Dr. George E. Ebright, San Francisco, president of the State Board of Health, takes the stand that the repeal of the isolation ordinances would be a deadly menace to the health of the community. He says that the carriers in San Francisco quarantined at the Isolation Hospital are comfortable and are treated with the greatest care. The State Board has found little difficulty in controlling diphtheria in other parts of the state, but little opposition having arisen on account of attempts at regulation.

ILLINOIS

Personal.—Dr. Frank A. Stubblefield, medical director of the Alton State Hospital, who has been ill in St. Joseph's Hospital, Alton, is reported to be improving.

---

[1] Rust, E. W.: Edible Snails, Yearbook U. S. Dept. Agric. for 1914, p. 491.

Foot and Mouth Disease.—Two herds of Guernseys and Holsteins, 204 in number, belonging to Arthur Meeker, found to be infected with foot and mouth disease, have been slaughtered.——Of the Guernsey herd of Mrs. Durand, two have died from secondary infection and a stricter quarantine has been put into effect at Crab Tree Farm.——The animal health commissioner of Iowa has notified the assistant state veterinarian that there must be no exchange of stock of any kind between Illinois and Iowa, owing to the outbreak of foot and mouth disease in Illinois.

Chicago

Diphtheria Carriers.—Almost 500 diphtheria carriers have been discovered among the schoolchildren of Chicago since the opening of school on September 7, according to the records of the department of health.

New Armory Dedicated.—Field Hospital Companies Nos. 1 and 2, Ill. N. G., dedicated their new armory in Chicago, October 1. Major William J. Swift, M. C., Ill. N. G., commanding Field Hospital No. 1, presided as toastmaster.

Personal.—Dr. John A. W. Fernow was painfully injured in a collision between street cars, October 3, but rendered first aid to the others who were injured.——Dr. Anthony Balcerzak has been elected chief medical examiner of the Polish National Alliance.

KANSAS

Personal.—Dr. Joseph M. McKamey, Kingman, sustained a skull fracture in a collision between his motor car and a train, September 12.

Baby Week at Topeka.—During baby week, held at Topeka, October 5-8, under the auspices of the State Board of Health Division of Child Welfare, Dr. Lydia Allen DeVilbiss, director, and Dr. Harold B. Wood, 159 babies were registered for examinations. Picture films were lent by the National Association of Tuberculosis, Cincinnati Department of Health, Kansas State Board of Health and the University of Kansas. There was an exhibit of A. M. A. placards (cartoons), other placards, and sketches and water color designs by Dr. Wood. There were also displays of baby clothing and furniture and a pure milk exhibit. Programs were given afternoons and evenings.

KENTUCKY

Personal.—Dr. James Bruce has been reappointed house physician and chief of interns, at the Louisville City Hospital, succeeding Dr. Thomas L. Harris, resigned.——Dr. John H. Taylor, Providence, was operated on September 13, in St. Mary's Hospital, Rochester, Minn. The gallbladder and appendix were removed.

Hospital Notes.—A contract for a new tuberculosis hospital at Henderson was awarded September 15.——A hospital is to be built at once in connection with the Stuart Robinson College, Mission School, Blackey, near Whitesburg. About $10,000 is to be expended for hospital and equipment.——Dr. Thomas O. Helm, Bowling Green, has disposed of his lease and interest in St. Joseph's Hospital to Drs. Morton M. and Robert C. Moss.

New State Officers.—The sixty-fifth annual meeting of the Kentucky State Medical Association was held in Louisville, September 21 to 24, under the presidency of Dr. John J. Moren, Louisville, who at the first session yielded the chair to the president-elect, Dr. James W. Kincaid, Catlettsburg. Hopkinsville was selected as the next place of meeting and the following officers were elected: president-elect, Dr. Ap Morgan Vance, Louisville; vice-presidents, Drs. Myrvin E. Hoge, Quicksand; Amos M. Davis, Denton, and James B. Mason, London; secretary, Dr. Arthur T. McCormack, Bowling Green (reelected); delegates to the American Medical Association, Drs. Carl Lewis Wheeler. Lexington; and W. W. Richmond, Prestonsburg; councilor for the Fifth District, Dr. Charles W. Hibbitt, Louisville; nomination for members of the State Board of Health, Drs. Charles Z. Aud, Cecilia; Daniel M. Griffith, Owensboro; and Robert C. McChord, Lebanon. Dr. Edwin A. Stevens, Mayfield, was selected as orator in medicine; and Dr. William L. Gambill, Jenkins, as orator in surgery.

MASSACHUSETTS

Changes in Harvard Faculty.—The Harvard corporation has made the following appointments for the year opening September 27: Dr. John L. Morse, formerly associate professor of pediatrics, has been made full professor.——Dr. Frederick T. Lewis, formerly assistant professor of embryology, has been appointed associate professor.——Dr. John Warren, assistant professor of anatomy, has been made associate professor.——Dr. John L. Bremer, assistant professor of histology, has been made associate professor.——Dr. Francis W. Peabody has been appointed assistant professor of medicine and Dr. Herbert S. Langfeld, assistant professor of psychology.

Personal.—Dr. Fred P. Moore, Foxboro, has been appointed health supervisor of schools of Des Moines, Iowa.——Dr. Clarence H. Leland, Lowell, was severely cut and bruised by the overturning of his automobile in Lexington, September 13.——Drs. Roger I. S. Lee and Charles A. Porter, Boston, members of the Harvard Medical unit, returned from abroad, arriving in New York September 12.——Dr. William H. Devine, Boston, has been appointed director of school physicians by the Boston School Board.——Dr. Henry Colt, Pittsfield, has been appointed medical examiner for Berkshire County.——Dr. Milton J. Rosenau has resigned as a member of the Public Health Council of Boston and has been succeeded by John T. Wheelright.——Dr. Thomas F. Harrington, Boston, deputy commissioner of labor and industry, has been seriously ill at his summer home in Lynn with ptomain poisoning complicated with appendicitis and phlebitis.——Dr. Moses G. Parker, Lowell, was reelected president of the Parker Historical and Gynecological Society at the fifth annual reunion held in Lexington.——Dr. Lemuel F. Noble, Boston, has returned after several months' war service in Europe.——Dr. Francis D. Donoghue, Boston, arrived in New York from Europe, September 2.

MARYLAND

Meeting of Faculty.—The semi-annual meeting of the Medical and Chirurgical Faculty of Maryland will be held in Westminster, October 28.

University of Maryland Medical School Reopens.—The formal opening exercises of this institution were held October 6. Dr. Arthur M. Shipley, acting dean, presided, and the speakers were Dr. Randolph Winslow, of the University of Maryland, Dr. Harry Friedenwald, of the College of Physicians and Surgeons, and Dr. Ridgely B. Warfield, of the old Baltimore Medical College.

Protest Against Dr. Jones' Removal.—The Baltimore City Medical Society held a special meeting on October 1, adopting resolutions indorsing warmly the services rendered by Dr. C. Hampson Jones, as assistant health commissioner and protesting against his removal. The meeting was marked by intense feeling. The society has appealed to Dr. John D. Blake, the new commissioner of health, to use his prerogative by reappointing Dr. Jones.

Mosquito War Near End.—The first move to end the mosquito work has been completed and fifty inspectors have been laid off. The force will probably be broken up October 15. Sanitary Engineer W. D. Wrightson of the U. S. Public Health Service and his four inspectors will remain on duty until that date. Maj.-Gen. Wm. C. Gorgas, Surgeon-General of the U. S. Army and Surgeon-General Rupert Blue, of the U. S. Public Health Service, will make a final inspection of the work before that date.

Personal.—Dr. William H. Welch of Baltimore, a member of the Rockefeller Medical Mission, who is on his way to China, has reached Tokyo, Japan, where he with the other members of the mission were entertained by the Japanese premier.——Dr. John D. Blake, Baltimore, has been appointed commissioner of health by the mayor, to succeed Dr. Nathan R. Gorter. Dr. Gorter has been appointed a member of the State Board of Health by Governor Goldsborough. ——Dr. Robert H. Crawford, Baltimore, has returned after several months' duty with the Red Cross unit in Silesia.

MISSOURI

Cancer in Missouri.—The department of preventive medicine of the University of Missouri, as a part of the campaign against cancer in that state, has published in the University *Bulletin* a special article on the early diagnosis of cancer, by a member of the faculty of the university. The purpose of the bulletin is to call the attention of the laity to the general subject of cancer and especially to the importance of regarding the earliest symptoms. The bulletin especially warns the people against quacks and bogus testimonials regarding the cure of cancer.

St. Louis

Hospital Unit Not Needed.—The St. Louis University hospital unit, recently organized for service abroad, has been notified by the director-general of the royal army medical staff that for the present he is unable to use any more American hospital units.

Memorial Resolutions.—At a joint meeting held by the board of trustees and staff of the St. Louis Eye, Ear, Nose and Throat Infirmary, September 22, resolutions were adopted setting forth the high and honorable standing of Dr. Horatio N. Spencer and expressing deep sorrow at his death.

Personal.—Dr. Malvern B. Clopton sailed from New York September 25 for work with the American ambulance in Paris.——Dr. Guthrie McConnell has been placed in charge of the pathologic and bacteriologic laboratory of the Waterloo (Iowa) Medical Society.——Dr. Frederick Hagler has returned after six months' work in military hospitals in Serbia.——Dr. Milton Schaic has resigned as medical director of the Jewish Home for Chronic Invalids and Consumptives of St. Louis.——Dr. Ralph L. Thompson has returned from service in the British War Hospital in France.

NEVADA

To Muzzle Dogs.—The State Board of Health and the Hygienic Laboratory, September 18, issued a bulletin calling attention to the necessity for muzzling all dogs, on account of the prevalence of rabies, chiefly among coyotes. The disease existed in many parts of the state, it is said.

State Sanitary Survey.—Surgeon Carroll Fox, U. S. P. H. S., has completed a sanitary survey of the state in company with Dr. Simeon L. Lee of the State Board of Health. He believes that the State Board of Health should be completely reorganized; that the State Hygienic Laboratory, and Pure Food and Drug Commission should be placed under the control of the State Board of Health instead of the State University, and that a state sanitary engineer should be appointed. Dr. Fox, in his report, called attention to the fact that Nevada is the most poorly equipped state in the Union in the matter of its health service; that the State Board of Health was allowed an appropriation of only $6,500 while the Fish and Game Commission was allowed $8,000, and furthermore, that the latter commission expended last year $10,000 above this appropriation and the succeeding legislature passed a bill approving the extra expenditure. In the belief of Dr. Fox, at least $14,500 should be appropriated for the State Board of Health.

NEW YORK

Personal.—Dr. Smith Baker, for more than forty years a practitioner of Whitestown and Utica, announced his retirement from practice, September 25.——Dr. Alexander C. Calisch, Oswego, has been appointed a member of the Board of Civil Service Commissioners.

Psychopathic Ward Needed.—Drs. Walter S. Goodale and B. Ross Nairn, Buffalo, appeared before the aldermanic finance committee, September 23, to endeavor to secure an appropriation of $2,000 for the establishment of a psychopathic ward for suspected insane and alcoholic cases at the Buffalo Municipal Hospital.

New York City

Crile Speaks Before Academy.—At the stated meeting of the New York Academy of Medicine, October 7, Dr. George W. Crile, Cleveland, delivered the Wesley M. Carpenter lecture on "Kinetic Drive—Its Phenomena and Its Control."

Personal.—Dr. Louis T. Klinker has suffered a mental breakdown and has been taken to Bellevue Hospital for observation.——Dr. Abraham L. Wolbarst began a series of public genito-urinary clinics at the West Side German Dispensary and Hospital, at 8:30 p. m. October 7. He also began a similar series of clinics on October 5, at 3 p. m. at Beth Israel Hospital and Dispensary.——Dr. Mary M. Crawford, Brooklyn, who has been serving for about a year in the American Hospital just outside of Paris, has returned to this country.——Dr. J. W. Brown, Dr. and Mrs. H. Holbrook Curtis and Dr. John E. Jones have sailed for Europe.

Columbia University Opens.—President Nicholas Murray Butler opened Columbia University's one hundred and sixty-second year on September 29 and in his address gave the assurance that within five years the project launched by the University and the Presbyterian Hospital for a great medical center will have been begun. He said that the $7,000,000 which the University must raise as its share would be forthcoming and added that plans had been adopted looking to the accomplishment of the task. Dr. Francis Carter Wood, director of the Crocker Cancer Research Fund, delivered the opening address to the students of the medical school, taking as his subject "Magic and Medicine." The point which he particularly emphasized was that the exploitation of radium cures of cancer by the lay press had been and was influencing many cancer patients to defer a resort to surgery, whereas in truth radium would cure but a small percentage of cancers and would do nothing which could not be done by surgery.

NORTH CAROLINA

Antityphoid Inoculation.—The State Board of Health reports that 47,037 patients were immunized against typhoid fever during the two first campaigns conducted by the State Board of Health.

Hospital Notes.—The Western North Carolina Methodist Conference, at its last meeting, advocated the establishment of a hospital in Salisbury.——The Tranquil Park Company has been organized at Charlotte to establish a hospital and sanatorium for the treatment of noncontagious medical diseases. Dr. John Q. Myers, Charlotte, is president and physician in charge of the institution; and Dr. John P. Munroe is vice president.——The Bloomsbury Sanatorium is under course of construction and will be ready to receive patients by the first of January. It is located on a site of 15 acres of rising ground near Bloomsbury.

OHIO

Lumber Magnate Donates Site for Hospital.—Peter Kuntz, Middletown, has purchased forty acres of land west of Dayton, which he has donated to the Sisters of the Poor of St. Francis, for a hospital. About $500,000 will be expended for the institution.

License Restored.—At its meeting July 6, the Ohio State Medical Board voted to restore the license of Dr. J. C. Ludwig of Cincinnati, which was revoked in 1907, for reasons involving moral turpitude. Many prominent citizens of Cincinnati endorsed his application for restoration. He is 77 years of age.

Not to Use Title of "Doctor" or "M.D."—The Ohio Board has adopted a regulation that limited license certificates will not confer the right to use the title "Doctor," "Dr.," "M.D.," "Physician" or "Surgeon." The regulation provides, however, that licensed practitioners in the limited branches on their cards, office signs, letter heads or elsewhere, may use the name of the limited branch specified in their certificates and may properly sign themselves as indicated.

Registration of Limited Practitioners.—In accordance with the Platt-Ellis law which gives the State Medical Board of Ohio the duty of registering practitioners of the various medical cults, blanks have been sent out to all such practitioners in order to secure a complete record. The cults mentioned in the law are chiropractic, naprapathy, spondylotherapy, neuropathy, mechanotherapy, electrotherapy, hydrotherapy, suggestive-therapy, psychotherapy, magnetic healing, massage, Swedish movement, chiropody and optometry.

Infantile Paralysis.—September 25, it was reported from Cleveland, that sixty-five homes had been quarantined by the City Health Department on account of infantile paralysis in the section of the city known as Willoughby. The death rate had been 6 per cent., which was 2 or 3 per cent. higher than the normal mortality rate. Health Commissioner Ford issued instructions as to personal prophylaxis. At Canton, September 23, the Board of Health ordered the quarantine of eight homes in which cases of infantile paralysis had occurred since September 1. In the previous week no new cases of the disease had developed. The order to quarantine these homes came from the State Board of Health.

Personal.—Dr. Oscar Theodore Schultz, formerly assistant professor of pathology in Western Reserve University, Cleveland, has been appointed professor of pathology and bacteriology in the College of Medicine of the University of Nebraska, Lincoln and Omaha.——Dr. David Marine, Cleveland, has returned from Compiegne, France.——Dr. Harry H. Snively, Columbus, in charge of the American Red Cross Hospital at Kiev, Russia, is said to have been made a general officer by the Russian government.——Dr. John F. Beachler, Columbus, fell down stairs, September 10, and sustained severe injuries.——Rev. Michael V. Halter, formerly a physician of Akron, has been appointed temporary pastor of Holy Trinity Church, Avon.——Dr. Howard W. Arndt, Lore City, was seriously injured in a collision between his automobile and a street car at Lore City and is under treatment in a Cambridge hospital.——Dr. Sylvester R. Best, Centerburg, has been appointed chief statistician for the Department of Vital Statistics.

PENNSYLVANIA

Hospital Cornerstone Laid.—The cornerstone of the Philadelphia Memorial Hospital, the gift of 11,200 Philadelphia Free Masons, was laid, September 29, with impressive ceremonies, on a part of the large tract dedicated to the care of dependent Masons, at Elizabethtown, Pa.

Changes in Pittsburgh University Faculty.—Dr. John Jenkins Buchanan, for fourteen years professor of surgery in the University, has resigned as an active teacher and has been elected professor emeritus.——Dr. Robert Talbott Miller, for the past five years a member of the surgical faculty of the School of Medicine, and lately appointed associate professor of surgery, has been appointed full professor in charge of that department.

Infantile Paralysis.—The outbreak of infantile paralysis at Erie and in that vicinity has about subsided and Drs. Fox and Rivas, sent by the State Board of Health to take charge of the situation, left Erie September 24. It was believed that very few additional cases would occur if the people took the proper hygienic precautions about which they were carefully instructed by the two experts. No new cases had been reported since September 15. Altogether there have been fifty-nine cases in the city and fifteen in the county outside, since January, 1915.

Philadelphia

Reception of Medical Club.—The Medical Club of Philadelphia will give a reception, October 15, in honor of Surgeon General Rupert Blue, United States Public Health Service, and Rear Admiral William C. Braisted, Surgeon General, United States Navy.

New Scholarships at Women's School.—Through friends of the Women's Medical College, two new scholarships are this year available for women students. The scholarships carry with them the sums of $225 and $250 a year, respectively. The faculty of the college will choose recipients from the list of applicants.

New Law on Communicable Diseases.—The Department of Public Health and Charities has issued a pamphlet edition of "An Act to safeguard human life and health throughout the commonwealth, by providing for the reporting, quarantining, and control of certain communicable diseases, and for the prevention of infection therefrom, and prescribing penalties for violations of the act," approved May 28, 1915.

Personal.—Dr. John A. Kolmer has been appointed assistant professor of experimental pathology in the University of Pennsylvania.——Dr. L. D. Englerth has been appointed chief resident physician to the Frankford Hospital.——Dr. E. E. Montgomery was operated on for hernia in Jefferson Hospital, recently.——Dr. William C. Hollopeter, for fifteen years professor of pediatrics at the Medico-Chirurgical College has resigned and has been succeeded by Dr. James H. McKee.——Dr. William B. Swartley is on his way to join the staff of the American Ambulance Hospital in France, where he will remain about three months.——Dr. Charles K. Mills, having resigned his chair in the Medical School of the University of Pennsylvania, will devote attention to postgraduate teaching, research work and private practice.

RHODE ISLAND

State Society Holds Fall Meeting.—The Rhode Island Medical Society held its fall meeting at St. Joseph's Hospital, Providence, September 2, after dinner and sports at Hillsgrove.

Infantile Paralysis.—The occurrence of fourteen cases of infantile paralysis at West Warwick resulted in an investigation by members of the State Board of Health. It was found that there was no association of the cases, except that in two instances there were two patients in the same family. The disease could not be traced to any definite focus. None of the patients was over 7 years old.

Personal.—Dr. Olin S. Pettingill, assistant superintendent of the Rhode Island State Sanatorium, has been offered the position of superintendent of the Western Maine Sanatorium, Hebron.——Dr. Elisha A. Cohoon of the staff of the Rhode Island State Hospital has been appointed administrative officer of the psychopathic department of the Boston State Hospital and pathologist for the Massachusetts Board of Insanity.

TEXAS

For the Eradication of Infections.—A meeting of the State Board of Health and representatives of the federal government, representatives of the state agricultural and mechanical college and the live stock sanitary commission of Texas was called October 5 for the purpose of formulating a plan for the eradication of Texas fever, charbon, hog cholera, etc.

Personal.—Drs. Claude O. Harper, Thomas M. Jeter, Samuel A. Lundy, and Lyman A. Barber have accepted appointments as members of the board of health of Fort Worth.——Dr. Jake T. Wilhite has retired from the staff of the State Hospital, Austin, to accept the position of physician-in-charge of the Pasteur Institute.——Dr. Raleigh L. Davis has been appointed second assistant physician of the State Hospital, Austin; Dr. T. N. Miller, third assistant; and Dr. Wooten D. Lightfoot, fourth assistant physician.——Dr. Frank E. Piner, formerly city health officer of Denton, returned from war service in England, September 24.

The Situation at Galveston.—Mr. Charles Saville, director of sanitation of the city of Dallas, has made a report on the sanitary conditions at Galveston following the recent storm. He recommends that the water for drinking and cooking purposes be boiled; that systematic bacteriologic analyses of the city water be taken daily; that all water mains and dead-ends be flushed out; that the use of water from private wells and underground systems be interdicted, and that a sterilizing apparatus be installed at the water pumping station for the water supply of the city. He also recommends the construction of dry closets; the systematic flushing and cleaning of sewers and catch basins; the keeping of garbage and refuse in fly-tight receptacles; the incineration of all garbage and refuse; the removal of sand from the city streets and the establishment of a high temperature refuse incinerator for permanent use.

WISCONSIN

Free Silver Nitrate.—The State Board of Health has notified the local boards of health that a 1 per cent. solution of silver nitrate will be furnished free of charge to all physicians and midwives in the state.

Personal.—Dr. Argo M. Foster, Racine, who was injured in a collision between his automobile and an electric car in August, has been obliged to undergo an operation on the skull and is under treatment in a Chicago hospital and is said to be doing well.

Legislation Helps Sanatoriums.—Five new county tuberculosis sanatoriums will be erected in Wisconsin this fall, in Marathon, Grant, Jefferson, Dunn and Fond du Lac counties. In four of these counties the county board members are already at work on the proposition and in the fifth county, the county medical society and private citizens have taken the initiative.

Madison Does Not Want Polluted Drinking Water.—Medical men of Madison, at a meeting September 9, passed resolutions based on the proposition to exchange the artesian water supply for Madison for surface water from Lake Mandota; and setting forth that the present supply is pure, that its cost is moderate and that there is an abundant supply. Furthermore, that Lake Mandota is polluted by the sewerage of the State Hospital for the Insane and the residences around the lake. They, as physicians of Madison and the vicinity, and members of the Dane County Medical Society, believe that the change proposed is perilous, and call on the city council to retain the present source of water supply, to establish a modern and adequate plant in charge of a competent sanitary engineer.

CANADA

Personal.—Dr. William Henderson, Sarnia, Ont., who has a commission with the Royal Army Medical Corps in England, has been appointed physician-in-chief of a hospital ship for the Dardanelles. The ship carries six physicians, twelve nurses and has 450 beds.——Prof. Thomas G. Brodie, F.R.G.S., and Prof. John J. MacKenzie, B.A., M.D., will shortly return from England to resume their duties at the University of Toronto. Both professors went over as supernumeraries with the University of Toronto Base Hospital.——Dr. Fortunat Lachance, Winnipeg, mayor of St. Boniface, Man., will shortly leave for the front in charge of one of the departments of the military hospital being equipped by Laval University, Montreal. Dr. Lachance will have the rank of lieutenant-colonel.——Col. John T. Fotheringham, Toronto, chief medical officer of the Second Canadian Overseas Force, writing to Dr. Goldwin W. Howland, Toronto, says that Lord Kitchener and the inspector-general of the War Office have stated that the second force now in France both in training and physical fitness was the finest body of men that had left England for France, a place of honor up to this time held by a division from Ulster.——Dr. Robert G. Brett, Banff, is to be appointed the next lieutenant-governor of the province of Alberta.

Ontario Medical Commission Appointed.—The Ontario government has at last appointed its long-promised commission on the subject of medical education and practice in that province. The commissioner is the Hon. Mr. Justice Hodgins of the supreme court of Ontario. Wide powers are given to the commissioner as seen in the instructions issued with the appointment. To inquire into and report on all or any matters relating to education for the practice of medicine in or affecting the province of Ontario; the construction, powers, duties and regulations of any body corporate or incorporated and of any faculty or department thereof having any relation to medicine, the exercise of the same and the revenues and expenditures thereof; the situation, legal or otherwise, of such bodies in regard to each other or to the province; the establishment, creation, control and regulation of any new body intended to have relation to medicine; the existing or possible methods of examining, licensing or otherwise authorizing the carrying on by individuals of the practice of any methods having any relation to medicine and the standards prescribed and followed or proper to be established and followed; the present positions, status and practice of osteopaths, dentists, nurses, opticians, optometrists, chiropractors, Christian Scientists or others practicing or professing medicine; the existing laws of Ontario in relation of any of the foregoing and their practical operation; any matter arising out of the foregoing which it is necessary to investigate with a view of the above inquiries.

Hospital News.—In his public address in Toronto on September 27 the prime minister of Canada, Sir Robert Borden, referred to the work of the Canadian hospitals abroad. Canada has established in Great Britain, France and at the Dardanelles no less than sixteen hospitals. These are for all the forces of the British empire and not for Canadians alone. Eight of them are located in Great Britain; five are in France; three are at the Dardanelles. On the staffs of those hospitals are 2,400 Canadians, and 525 trained nurses. Sir Robert stated that he had visited nearly fifty hospitals while abroad and he considered that none were better equipped, better organized, or in which the wounded received better care and attention than the hospitals which have been organized by the people of Canada.——At Hamilton, Ont., the cornerstone of a new hospital was laid on September 24 by the lieutenant governor of the province, Sir John Hendrie. The new institution will be known as Mt. Hamilton Hospital. It will be the center of a group which it is intended to establish there. The hospital is maintained in its entirety by the civic administration. Dr. Charles O'Reilly, Toronto, formerly superintendent of the Toronto General Hospital, was present and delivered an address. Dr. O'Reilly went from the Hamilton General Hospital many years ago to the Toronto General as superintendent.——The Massey-Harris employees, Toronto, are to establish in England a convalescent home for wounded Canadian soldiers. The yearly maintenance will be about $50,000, and the original cost of equipment about $25,000. Canadian doctors and nurses will be employed.

GENERAL

Ohio Valley Physicians' Meeting.—The seventeenth annual meeting of the Ohio Valley Medical Association will be held in Evansville, Ind., November 3 and 4, under the presidency of Dr. E. Otis Smith, Cincinnati.

Colored Physicians Hold Meeting.—The annual meeting of the National Medical Association was held in Chicago, September 1 to 3. Dr. Ulysses G. Dailey, Chicago, was elected president; Dr. Walter G. Alexander, Orange, N. J., secretary; and J. R. Levy, Winston-Salem, N. C., treasurer. The association will hold its next meeting in Kansas City, Kan.

Roentgenologists Elect Officers.—At the annual meeting of the American Roentgen Ray Society held in Atlantic City, September 23 to 25, Dr. Augustus W. Crane, Kalamazoo, Mich., was elected president; Dr. William A. Evans, Detroit, treasurer, and Dr. F. W. Manges, Philadelphia, was reelected secretary. Cincinnati was selected as the place of meeting for next year.

Clinical Congress of Surgeons.—The sixth annual session of the Clinical Congress of Surgeons of North America will be held in Boston during the week of October 25. The mornings and afternoons will be devoted to clinics and four evening meetings will be held. On October 25, the president-elect, Dr. Charles H. Mayo, Rochester, Minn., will deliver the annual address.

Missouri Valley Physicians Elect New Officers.—At the annual meeting of the Missouri Valley Medical Association held in Des Moines, September 21 to 23, under the presidency of Dr. Granville Ryan, Des Moines, the following officers were elected: president, Dr. John P. Lord, Omaha; vice presidents, Drs. Charles G. Geiger, St. Joseph, Mo.; and Hobart A. Weston, Des Moines, Iowa; secretary, Dr. Charles Wood Fassett, Kansas City, Mo. (reelected); and treasurer, Dr. Oliver C. Gebhardt, St. Joseph, Mo.

Rockefeller Foundation Expenses for 1914.—The financial transactions of the Rockefeller Foundation show that the administration expenses for the year 1914 were $13,731.60; appropriations for the International Health Commission, $133,237.06, of which $36,651.96 went to the China Medical Commission and $10,000 was appropriated for research work on governmental problems; for war relief there was expended $994,613.06 and for purchase of the Bird Refuge in Louisiana, $224,886.95. The total expenses for the year were $1,421,031.81.

Electro-Therapeutists Hold Meeting.—At the annual meeting of the American Electro-Therapeutic Association held in Atlantic City, September 14 to 16, under the presidency of Dr. John W. Torbett, Marlin, Tex., the following officers were elected: president, Dr. Jefferson D. Gibson, Denver; vice presidents, Drs. J. Willard Travell, New York; Frank B. Granger, Boston; William L. Clark, Philadelphia; Sidney A. Twinch, Newark, N. J.; and William Martin, Atlantic City; secretary, Dr. Byron Sprague Price, New York; treasurer, Dr. Emil Heuel, New York (reelected), and registrar, Dr. Frederick M. Law, New York (reelected).

Conference on Social Hygiene.—The First Central States Social Hygiene Association will be held at the Congress Hotel, Chicago, October 25 and 26, under the auspices of the Central States Division of the American Social Hygiene Association. The first session of the conference will be held in the evening of October 25, and will be given over to discussions of general features of the social hygiene movement. In the forenoon of the following day, the moral and educational features of the social hygiene movement will be taken up; in the afternoon, the medical and public health aspects will be treated; the evening session will be given over to discussions of the legal and administrative phases.

Meeting of National Safety Council.—The fourth annual safety congress of the National Safety Council will be held at the Bellevue-Stratford, Philadelphia, October 19 to 21. At the general session on October 19 the subjects considered will include: The development of the safety idea; safety as an indispensable part of an efficient manufacturing organization; the safety idea as related to the credit of a business organization; vital importance of the visiting nurse in industrial work; and the standardization of safeguards. The other meetings of the council will be sectional meetings, to be composed of groups of persons interested in accident prevention problems as they affect special industries and will consist of experience meetings and discussions of various points involved. The final meeting on October 21 will be a general meeting of all sections to discuss the question "How to Educate the Workman."

New England Tuberculosis Conference.—The second New England Tuberculosis Conference will be held under the auspices of the National Association for the Study and Prevention of Tuberculosis, October 22 and 23, under the presidency of Dr. Stephen J. Maher, New Haven, Conn. The first session will be held at the Hotel Kimball, Springfield, Mass., and will take up methods of antituberculosis work. At a second session held on the ninth floor of the Forbes and Wallace department store on Kinshon Street, sales methods of the Red Cross seal will be described. The third session will be held in the First Congregational Church at which the topic for discussion will be "Industry and Tuberculosis." The fourth and fifth sessions will be held at the Westfield Sanatorium and at these sessions programs of antituberculosis work and the diagnosis of incipient cases of pulmonary tuberculosis will be considered.

Candidates for Army Medical Corps.—The following candidates, who have passed the preliminary examination for appointment in the Medical Corps of the Army, have been invited to attend the 1915-1916 session of the Army Medical

School, Washington, D. C.: Arden Freer, Bellevue Hospital, New York City; John S. Caul, Laceyville, Pa.; Charles C. Hutter, 245 West North Avenue, Chicago, Ill.; Harvard C. Moore, 623-624 Medical Building, Portland, Ore.; William F. Rice, Government Hospital for the Insane, Washington, D. C.; Charles G. Sinclair, Providence Hospital, Washington, D. C.; Edward A. Noyes, 818 Lombard Street, Portland, Ore.; *Joseph L. Furden*, 1633 Monroe Street, Washington, D. C.: Herbert H. Bauckus, Town Line, Erie County, N. Y.; Robert P. Williams, 1616 North Second Street, Harrisburg, Pa.; Frederick H. Petters, 100 High Street, Buffalo, N. Y.; Edwin B. Maynard, first lieutenant, M. R. C., Fort Benjamin Harrison, Ind.; Walter E. Koppenbrink, 5324 Bartmer Avenue, St. Louis, Mo.; Frank W. Wilson, U. S. Soldier's Home, Washington, D. C.; Clarence S. Ketcham, Union Protestant Infirmary, Baltimore, Md.; Luther M. Ferguson, 91 Arlington Street, Newton, Mass.

Examination for Medical Corps of the Navy.—The next examination will be held Nov. 15, 1915, at Washington, D. C.; Boston, Mass.; New York, N. Y.; Philadelphia, Pa.; Norfolk, Va.; Charleston, S. C.; Great Lakes (Chicago, Ill.); Mare sland, Cal., and Puget Sound, Wash. Applicants must be itizens of the United States, and must submit satisfactory vidence of preliminary education and medical education. The first stage of the examination is for appointment as assistant surgeon in the Medical Reserve Corps and embraces he following subjects: (a) anatomy, (b) physiology, (c) materia medica, (d) general medicine, (e) general surgery, and (f) obstetrics. The successful candidate then attends a ourse of instruction at the Naval Medical School, during which course he receives a salary of $2,000 per annum, with allowances for quarters, heat and light, and at the end of the ourse, if he successfully passes an examination in the subects taught at the school, he is commissioned an assistant urgeon in the Navy. Full information with regard to the physical and professional examination may be obtained by addressing the Surgeon General of the Navy, Navy Department, Washington, D. C.

Pediatric Clinical Meeting.—A meeting of pediatricians of he central and western states will be held at Chicago, Octoer 15 and 16. On the evening of October 15 a permanent organization will be effected at a meeting to be held in the Auditorium Hotel. Clinics will be held at the various pediatric centers throughout both days.

Bequests and Donations.—The following bequests and donations have recently been announced:

Brooklyn Eye and Ear Hospital, $5,000; Brooklyn Hospital, Home for Consumptives and Home for Aged Men and Aged Couples, each $2,500 by the will of Robert B. Woodward.

The German, St. Luke's, Roosevelt and Presbyterian hospitals, New York City, each an equal share in the estate of $231,158 by the will of Henry Miller.

Mexican Relief Fund, $25,000, a donation from the Rockefeller Foundation.

Hospital of the University of Pennsylvania, several beds endowed in memory of her husband, Dr. George M. Stiles, Cohocton, by the will of his widow, Mrs. Amanda Stiles.

Medico-Chirurgical College of Philadelphia, conditional bequests amounting to $150,000.

Henderson (Ky.) City Hospital, a donation of $15,000 by a citizen providing the city donate a similar amount.

Washington, D. C., Home for Incurables, $2,000 to establish the George Riggs Memorial Room; Episcopal Eye, Ear and Throat Hospital, $2,000, and Georgetown University, $4,000 for the maintenance of the Elisha Francis Riggs Memorial Hospital, by the will of Medora Riggs.

American First Aid Conference.—The American First Aid Conference referred to in these columns two weeks ago is calling on state societies for their cooperation in the form of a small committee to cooperate with the proposed organization. The following questions are also being sent to the chief surgeons of railroads, mines and manufacturers and others:

1. What has been your experience with the most available first-aid package and dressing for small and large wounds?
2. What has been your experience with the immediate employment of antiseptics in accidental wounds; what antiseptic have you used, in what strength, and how applied? Have you employed tincture of iodin; if so, how and what have been the results?
3. What in your experience has been the most efficient and most readily applied method of fixation for injuries of the (a) upper and (b) lower extremity?
4. Have you considered the construction of a stretcher, which, in addition to serving as a means of transportation of injured, will have appliances for the fixation of the upper and lower extremity, somewhat along the lines of a Bradford splint, or the Gihon naval splint?
5. Please state your views on some liquid ointment dressing which would be available for first aid in large wounds and burns with the object of preventing the usual dry-gauze dressing adhering to the wound and rendering subsequent dressings painless.

The committee asks that each question be answered on a separate sheet—each sheet signed. Those who have suggestions to make as regards this important subject should write to the secretary, Dr. Joseph C. Bloodgood, 904 North Charles Street, Baltimore.

A Real Medical Reserve Corps for the Navy.—Steps have been taken by the Navy Department to make the Medical Reserve Corps a reserve in fact for the Medical Corps of the Navy. Under the terms of a circular just issued by the department, medical reserve officers are required to bind themselves to perform active duty in the Navy whenever they are called upon by the secretary. Officers of the Medical Reserve Corps are also required to report to the Navy Department at least once in every six months as to their location and their physical fitness for military duty. Their number is limited to 300, and they are to be honorably discharged at the age of 55 years. In outlining the duties of the Medical Reserve Corps the circular says:

> When the president of the United States signs and confers a commission in the Naval Medical Reserve Corps he does so with the full realization that he is placing special trust and confidence in the ability and patriotism of the individual to whom the commission is issued, and, whether in peace or in war, this medical officer enjoys the prestige and standing that results from such recognition. Officers of this corps receive no financial return except when on active duty, and during time of peace, the number so assigned will necessarily be limited. But it is believed that love of country and pride in the possession of such a commission will influence the best among the medical profession to accept this honor and responsibility, whereby they may keep in close touch with the Navy Department, and thus be prepared to serve their country in a national emergency. Every officer of the Medical Reserve Corps will, *on appointment*, be required to bind *himself* to be subject to the laws and regulations governing said corps and to perform active duty in the Navy when called upon, at any time during a period of at least five years from date of appointment, during which period such officer will not be honorably discharged from the Medical Reserve Corps except *for physical disability* in the event that his services should no longer be required; this regulation, however, not to prevent any officer who desires to do so from submitting his resignation at any time. After five years from date of appointment, the resignation of any officer of the Medical Reserve Corps will, in the absence of special circumstances, be accepted when submitted. However, the acceptance of an officer's resignation is in all cases discretionary with the president.

FOREIGN

Deaths in the Profession Abroad.—Among those who have been killed while tending the wounded in the field is G. Heimann of Berlin, one of the pioneers in eugenics, and Prof. H. Piper of the Institute for Physiology, at Berlin. Piper's work on the physiology of the senses is well known, especially the results of application of the filament galvanometer in study of this subject.

Training Women Laboratory Helpers in Germany.—The Woman's College at Leipzig offers a special four semester course of training in all the branches needed in laboratory work. This Hochschule für Frauen is said to be especially well equipped for the purpose, as also for fitting trained nurses for superintendents' positions. The laboratory course includes, besides the usual branches, microphotography and Roentgen-ray work.

Imposters Seek to Benefit by Dearth of Physicians.—The *Deutsche medizinische Wochenschrift* states that one of the annoying by-effects of the prevailing lack of duly qualified medical men at many points is that impostors have sought to pose as regular physicians. Forged credentials and diplomas have been presented to the authorities at Leverkusen and elsewhere and the *Wochenschrift* warns of the necessity for being wary for a time in making appointments to medical positions or summoning a new physician.

List of Latin-American Physicians.—A series of manuscript consular reports on druggists, pharmacists, physicians, surgeons and dentists, which has been collected by the Bureau of Foreign and Domestic Commerce, Washington, D. C., includes the following Latin-American countries: Honduras, British Honduras, Cuba, Chile, Costa Rica, Dutch Guiana, British Guiana, Colombia, Nicaragua, Mexico, Dominican Republic, West Indies, Venezuela, Paraguay, Panama, Haiti, Salvador, Guatemala, Ecuador, Argentina, Brazil, Peru and Uruguay.

The New Public Health Department at Berlin.—About a year ago the authorities organized for the city of Berlin what is officially designated as the "Deputation für das städtische Gesundheitswesen" and the "Medizinalamt." The full-time medical officer appointed at the head of the system left for the front soon after the opening of the war, and there has been much dissatisfaction over his persisting absence from his post. He has finally returned and taken up his duties, and the municipal authorities have at last formally outlined the work for the new health department. It is to have under its care everything connected with the health of the populace, especially the supervision and promotion of the welfare of all municipal institutions and arrangements dealing with health and those supported by municipal funds. This includes welfare work for infants, for children of all ages before, during and after the school age, measures to repress alcoholism, tuberculosis and sexual diseases; further all measures to promote general hygiene (air, light, water, sewage disposal, food, housing, prophylaxis of epidemics, the disinfection system, food inspection, and finally, supervision of the municipal lodging house, workhouse, orphan asylums, hospitals, schools, bathing establishments, etc. The new Medizinalamt is practically the old municipal inspection system, and it is subordinate to the above department. The latter is expected to study and test all the questions arising in its sphere and to present its final decision to the municipal authorities, the magister or the single departments involved. The other departments and authorities are also expected to confer with this department before taking any important step that might affect the public health in any way.

WAR NOTES

Hospital for Wounded Aviators.—A convalescent home has been provided for wounded aviators in a chateau at Viry-Chatillon, Dr. Moujin, owner of the chateau, is medical director of the home.

Sanitary Commission to Leave Serbia.—Dr. Richard P. Strong, head of the American Sanitary Commission in Serbia, has sailed from Naples on his way home. He says that the majority of the American physicians who have been engaged in Red Cross work in Serbia, will leave that country by October 10.

German-American Hospital Unit Starts for the Front.—A delegation of physicians and nurses sent by the American Physicians' Expedition Committee sailed for Europe, from New York, September 9. The medical staff of the unit consists of Drs. Herman Fischer, Louis Brooks, Joseph J. Ling, J. L. Mathesheimer, together with four nurses.——Dr. William L. Bulach, New York, sailed on the same steamer to offer his services for work for the Red Cross abroad.

Heliotherapy for the Wounded.—An institution has been fitted up at Dürrheim in the Black Forest in Germany for systematic sunlight treatment of wounded soldiers and those with tuberculous lesions in the bones. The institution was organized by Bernhard of St. Moritz, who was the first to apply heliotherapy to war wounds, but his assistant, W. Staehelin, is now in charge. Dürrheim is over 2,000 feet above sea level. Torpid wounds, fistulas and delayed healing from any cause are regarded as indicating heliotherapy, as are also injuries from gangrene, frost bite and action of caustics, and large persistently secreting wounds.

Great Britain Needs More Surgeons.—Sir James Barr, vice president of the British Medical Association, in an appeal for surgeons for armies going abroad, says that 2,500 will be required, and that there will be no course open but to apply to the United States to fill the necessary complement of medical men if Great Britain cannot produce the requisite doctors.——The *Lancet*, in its issue of August 28, states that the medical schools will be very short of students on account of the large number of young men, of the educated class, who have joined the army. The future will see an increased demand for medical men, and consequently a greater prospect of success.

Red Cross Items.—Hon. Ira Nelson Morris, American minister to Sweden, has completed arrangements with the Russian and Swedish governments to facilitate the journey to Petrograd of nine physicians, thirty-nine nurses and a large quantity of supplies sent by the American Red Cross.——The physicians and nurses of the American Red Cross mission to Germany, who came to Berlin after the close of the hospital at Gleiwitz and Kosel, were given medals by the German government, September 22.——The members of the American Red Cross units of Vienna and Budapest have been given similar decorations by the Austro-Hungarian government.——The American Red Cross unit, which has been stationed at Kiev, Russia, was moved to Makarov, September 15.

BEHIND THE BEYOND WITH THE BRITISH ARMY

[The following is from a Canadian medical student who is with a British army medical corps.]

The attitude of the surgeons and nurses toward the wounded in the war is commendable in the highest. I have not witnessed in civil hospitals so much tenderness and compassion toward patients as has been exhibited in dealing with these boys from the front. If a patient is a bit restless at the approach of anesthesia, the administrator will gently and quietly allay the nervousness by ways and means not often used at home. In the admission and examination tent where the chaps come in fresh from the trenches, disheveled, dirty and weak, their vitality and nervous energy at a low ebb, the senior surgeons will gain their confidence and good will on the spot by quiet, tactful and sympathetic questioning, terminating in the inevitable "We'll fix you up all right, old man." In the whole wide world of suffering there is no class of helpless more deserving and more in need of tender ministrations than this broken humanity—the first fruits of war. In this phase of the war, America will have a share of the glory. Recently a British Tommy told me he was in the Chicago Hospital (a British general hospital operated by doctors and nurses from Chicago) "where they are absolute bricks. After being up there on the line for months, you forget that there is that sort of kindness floating around." A Harvard unit nearby is very popular with English soldiers too.

There is an interesting tale about that part of the organization which lands the wounded in the reception tent, a process which involves gathering the wounded in "no man's land," in the trenches and back of them, nearly all accomplished at night by the glare of the sickly bluish-white flares of the enemy, often only by the rays of the moon—and sometimes no light of any kind looks down on the horrors of those bloody wastes of France when the gloomy task is accomplished by the sense of touch. The system includes, too, the field dressing station and the field ambulance train. The field dressing station may not be a station at all, but is far more likely to be an upturned stump, a rock, a bit of ruin, anything that will afford a slight protection. The base for supplies and billet is the cellar of a ruined building, a deserted barn or sometimes a plain dugout. Moreover, this is the farthest outpost of succor for the wounded, and is the most mobile department of the army medical corps, save the stretcher bearers, for it is right up behind the line and, from the nature of its service, advances and retreats with it.

The field ambulance corps is the mobile unit which connects the "gathering" system on the front with the "end of steel" located not so very many miles behind the line.

At the "rail head" is a casualty clearing hospital, which is the first part of the organization to present any elements of permanence. The hospital is under canvas and has a normal capacity for several hundred, but, like all military hospitals, its service must be very flexible, capable of undertaking to succor in some way many times its accustomed number. One of our patients told me that a few months ago, after a now famous battle, he saw 5,000 wounded under the care of one of these institutions. Hundreds were on stretchers, but most of them were lying in a field on the ground without even the protection of a great coat or blanket. They were awaiting their turn for succor, and before they had been there long, hot soup for their stomachs and sterile dressing for their burning wounds would appear from somewhere. Thus one can understand that after a period of stress, either offensive or defensive, the pressure on these hospitals is enormous, so much so that the wonder of the whole situation is not that the service becomes congested but that it is possible at all to "sort" the cases. The casualty clearing hospital, as its name implies, is really a sieve from which patients are distributed to hospitals in the rear. In feverish haste the wounded are rushed back, back, back anywhere to a place of comfort and at the same time relieving the stress on the casualty clearing hospital. Those but slightly injured are treated at this hospital and sent back to the line. Those who are severely stricken by wounds or disease are sent down to the larger and less mobile hospitals, which are able to render more appropriate treatment.

Naturally enough, the extent of injury or illness is really the determining factor which sends a man back to the front or to a stationary, general or base hospital or, joy be, perhaps to "dear old Blightey" (England in the vernacular of the trenches). The first few days of the rush after an engagement are always the most satisfactory from the doctor's view, for in it the wounds are almost all clean and the cases are in pretty good shape. But as time goes on and the dregs of the deadly business come filtering in, the state of the wounds gets worse.

In reality, these hospitals are little more than rest camps, for most of the patients never see a bed but remain on their litters during their stop, and none remain longer than seven days. A few nursing sisters are attached to these hospitals. By the way, these women are the only military women anywhere near the front, and they are miles and miles away from it. As already stated the casualty clearing hospital is a rest camp where wounds are dressed, good hot nourishing meals are served and cases sorted for final distribution. In comparison with other branches of the system, the casualty clearing hospital is a crude sort of place, but it is a cog necessary for the smooth efficiency of the great system.

The next link in the service is the ambulance train, which connects the casualty clearing hospital with the hospital farther removed from active operations.

The main business of war, however, is to kill, and for that purpose wounded soldiers are a drug on the market. The moment they are out of a job, they are in the ranks of the unemployed. With this conception of the enterprise in mind, it may be understood why the first considerations of the transportation system—the next link—is not for broken and useless humanity. It must stand aside for the ever needful "munitions of war" men, ammunition and food and all the trappings thereto. Those who have "done their bit" must make way for those who are on their way to do theirs.

Thus the transference of wounded from the front to the rear is not so much a matter of the needs of the patients as of the requirements of that mystic and voracious district—the front.

In the early days of the conflict—those days of stress on the British line—these trains had to yield precedence at every turn to troop trains. The ambulance trains would run a few miles, back onto a siding and wait, wasting hours while wounds cried out for dressings and men sick unto death lacked proper treatment. But the dispatch of these trains has improved much in the year, so that now within a few hours after departure the trains arrive at their destination, usually a general hospital about 50 miles from the front. Synchronously with the departure of the train a telephone message is sent from the casualty clearing hospital to the chief of the medical district to which the train has been assigned who, in turn, advises the hospitals in his zone to prepare for the reception of a convoy. These vestibuled trains are more than palatial ambulances on wheels—they are hospitals. They are equipped to serve meals and to perform emergency operations. The trains carry a staff of about thirty-five officers, nurses and orderlies, and have accommodation for about 300 lying down patients or 400 sitting up. The usual rate of unloading is 225 stretcher cases in the hour. The atmosphere of the ambulance train is one of cheerfulness, save for the silent dark coaches where lie the grievously stricken. You see, the boys are in hopes that they are bound for a sea-port town which in the near future will mean England.

One day we walked down by the quay where the spars stick up lone and thin, down among the fisher-folk of Picardy with their sabots and corsets (arm-pit high) and the smocks of the old men. For the first time we saw an ambulance train unload. A long siding had been built, and on this the train had been switched from the main line of the ———— Railway. A very long line of ambulances, of course all motor, was arranged along the dry clean gravel path, and these were quickly, quietly, and, be it said, gently filled with stretcher-cases by the Royal Army Medical Corps men under the direction of sisters and officers.

The poor Tommies fresh from the trenches were a pretty depressed lot. We waved to some and smiled to others, but no response was forthcoming. They were grimy and tanned brown, a severe contrast to their swathings. The boys were fagged out from their slow journey from the line. The drivers were without exception very careful of their charges. I must record, however, the very sympathetic behavior of the one woman driver. She handled her car so carefully and easily and treated those boys just as though they were her own. This incident inclines me to think that skilful women drivers would be just about the best for that sort of work.

On our way out we passed some American nurses in their pure white uniforms (they have taken over a hospital nearby and fly the Red Cross, Union Jack and Stars and Stripes). We were fortunate to get a ride on one of the laden ambulances bound for our camp. The villagers were awed as we whizzed through their sleepy street. The old curé stood with uncovered head as the car with the Red Cross passed him. The Tommies off duty removed their pipes and gaped quietly after us.

When the ambulances arrive at their hospitals they are quickly unloaded, and the patients are taken to the admission tent, examined and assigned to their wards. Thus this stream of broken humanity flows from its source (in the trenches) to the sea.

Prof. William Osler is visiting us now. His son is attached to our hospital and is a most likable young fellow —a sophomore from Oxford, by the way.

As I write we are awaiting a convoy, and I am on the "reception squad" tonight, that is, I am one of the youths who stay around, maybe half the night, taking stretcher cases out of ambulances and conducting walking cases to the various wards.

BERLIN LETTER

Berlin, Sept. 7, 1915.

Personal

Professor Gocht of Halle has been appointed to succeed the late Professor Joachimsthal as director of the orthopedic clinic of the university in Berlin.

Professor Piper, extraordinary professor of physiology, director of the division of physiology in the university institute and surgeon with the troops in the field, died on the field of battle, aged 38 years. His researches were conducted largely in the physiology of the organs of sense. He made some remarkable investigations in optics and acoustics and published interesting observations on the relationship between the physiology and psychology of the mind.

The War

EMPLOYMENT OF WOMEN PHYSICIANS

Female physicians will no longer be employed in the hospitals connected with the army medical department. The reason for this action is the fact that there is a sufficient number of male physicians available for such service, and that the female physician can be employed to better advantage at home in the care of women and children. It is quite likely that personal misunderstandings may have been in part responsible for this action of the army board.

HEALTH OF SOLDIERS

According to recent official reports, the health of the troops is entirely satisfactory in the West as well as in the East. The soldiers have been singularly free from extensive epidemics. Typhoid occurs in the West only very infrequently, much less so than a year ago. This must be ascribed to the improved hygienic and sanitary conditions now prevailing in the enemy's territory and the improved methods of living. Every effort has been made to provide the troops with suitable drinking water. Three hundred transportable drinking-water apparatuses, which furnish about 800 liters of cool, palatable and healthful water, have been furnished for this purpose. Each apparatus clarifies, sterilizes, cools and reaerates all kinds of water, thus making it suitable for drinking purposes. Where such an apparatus is not available, the sanitary authorities aim to lessen, if not prevent entirely, the dangers of poor drinking water. Some supplies are stopped entirely, others are improved by bettering the condition and locations of wells and by adding chemical substances to the water, making it potable. The medical corps is continually on the lookout for individual cases of diarrhea, and when found these patients are immediately isolated and the spread of any infection thus prevented. These measures are carried out not only with the troops, but also with the civil population in the enemy's country. Experienced sanitarians can be commanded in sufficient numbers to aid and further this work, not only by giving advice and counsel, but by placing their laboratories at the disposal of the army authorities. The medical corps is convinced that the generally employed vaccination against typhoid has done much to lessen the number of cases of this disease. During the period of mobilization of the troops, typhoid inoculation could not be done as well as it has been done since. All the troops have now been vaccinated, and the soldiers in training at home are vaccinated before they leave for the front.

CHOLERA IN THE EAST

In the East, particularly east of the Weichsel, cholera has spread rather rapidly among the civil population, and after the Russian evacuation of any city the German military doctors find many cholera patients, but the spread of the disease is very promptly checked by the measures employed elsewhere for the same purpose. Thus far cholera has not become epidemic. Of great value in the prevention of intestinal diseases has been the establishment of tearooms in all cities, towns and villages through which the soldiers pass on their way to the fighting front. Tea is prepared in large quantities in these places so that every soldier can have as much as he can drink. The fact that the troops have all been vaccinated against cholera must be accepted as one of, if not the principal reason, for the failure of the disease to become epidemic. Although the persons who have been vaccinated have not invariably received full protection against cholera, still, when they have contracted the disease, it has been in mild form only, with a rapid and uneventful convalescence.

Typhus fever is no longer a cause for apprehension. Every provision possible is being made at the front to provide opportunities for bathing and disinfection of clothing. If permanent bathing facilities cannot be had, temporary arrangements are made of which the soldiers can avail themselves. More than 100 bathing wagons drawn by horses are used for this purpose. They can be moved easily from place to place. Transportable laundries have also been provided in considerable numbers. Four hundred steam disinfection apparatuses are also in use. Wherever possible, provision is made to disinfect clothing, freeing it from lice and other vermin. In short, the measures employed to prevent the occurrence of typhus epidemics are now so far-reaching that little fear need be entertained with regard to this disease ever becoming epidemic. The control of tuberculosis, genitourinary diseases and nervous and mental diseases is very gratifying.

LONDON LETTER

London, Sept. 17, 1915.

The War

THE SUPPLY OF ARMY SURGEONS

The difficulty in obtaining a sufficient number of surgeons in the new armies still continues. As a consequence the age limit has been extended for home service from 50 to 55 years, and for foreign service from 40 to 45. Men who are over 55 and fit for additional work or some form of medical practice differing from what they are doing at present have been told that they can best serve their country by doing the work of younger men and releasing them for foreign service. The War Emergency Committee of the British Medical Association is working in cooperation with the War Office for the purpose of obtaining army surgeons. At its last meeting one of the suggestions made was to import physicians from America. The question of approaching the various government departments to release physicians under 45 now employed in various ways such as health officers, and educational medical officers, was also suggested.

THE INDIAN WOUNDED: PROVISION FOR THE PRESERVATION OF CASTE

The hospital at Brighton for the Indian wounded accommodates over 2,000 patients and differs in many ways from the ordinary military hospital. It is run by officers of the Indian Medical Service, assisted by a staff of assistant surgeons belonging to the Indian Subordinate Medical Department (which consists of natives and Eurasians), Indian nursing orderlies, storekeepers, water-carriers, sweepers, and others, numbering about 400. There is no female assistance, even laundry work being done by Indian washermen, especially brought over for the purpose. Many provisions have to be made so that the various castes can observe their customs which to them are of the highest importance. There are eight different kinds of diet and separate cookhouses for six different classes. The food of the patients is cooked in twenty-one cookhouses in the hospital grounds, and that of the subordinate staff in sixteen cookhouses. The Hindu cooks must in all cases be of the same or of a higher caste than the patients for whom they cook. The chief article of diet of all the fighting races in India is a kind of bread made from partially husked grain ground by hand between two slabs of stone. As regards meat all Mohammedans eat beef, but the practice is very abhorrent to Hindus, who regard the cow as a sacred animal. For this reason no beef is allowed in the hospital. Bacon and similar meat is also strictly prohibited. As Indians must themselves slaughter the sheep which they use for food, and they must do it in the special manner enjoined by their religious sects, they have to provide in the grounds of the county abattoir a new slaughter-house for this purpose. For Hindus the custom is to sweep the head of the animal off the neck with only one stroke of a talwar or sword, while for Mohammedans the mouth of the animal is pointed toward Mecca. As an Indian must bathe the greater part of the body before each time of prayer and a good Mohammedan must pray five times daily the amount of water used in the hospital averages between 60 and 70 gallons per head per day.

A YEAR'S CASUALTIES

The British casualties for the first year of the war are as follows: killed, died of wounds, etc., 70,992; wounded, 241,086; missing, 53,466; total, 365,544.

FOOD PRICES

Some time ago your Berlin correspondent gave some figures from a Swiss journal on the increase of food prices in this country since the war and compared them with the increase in Germany to the disadvantage of this country. They did not seem to be accurate. I am now pleased to be able to give official figures, both British and German, which show, as might be expected in consequence of the almost total cessation of her foreign trade, that the increase in Germany is the greater. According to the *Board of Trade Labour Gazette,* the general level of prices as compared with a year ago is about 23 per cent. higher, while the average increase in food prices, making allowance for their relative importance in working class houses, may be put at about 35 per cent. The latest available data concerning retail food prices in Berlin, published in the official Prussian *Statistische Korrespondenz,* show that, after a sharp rise in the first month of the war, prices declined somewhat last September, but from that month moved steadily upward until July, in which month they reached a figure representing an increase of nearly 70 per cent. on the prices of July, 1914. In Vienna, taking food prices in July, 1914, as equal to 100, the index number in July this year was 178.6. The rise in food prices in the early months of the war was much less marked in Vienna than in Berlin; in the second six months, on the other hand, the upward movement was considerably more pronounced.

PARIS LETTER

Paris, Sept. 16, 1915.

The War

MEASURES AGAINST MALINGERING IN THE ARMY

The attention of the minister of war has again been drawn to the instances of voluntary mutilation which tend to multiply among men in the army. Some soldiers have not hesitated to produce diseases in themselves in order to escape the performance of their duty. Thus there have been observed cases of jaundice caused by ingestion of picric acid, cases of facial dermatitis produced by the use of irritating substances and cases of conjunctivitis produced by the application of certain powders. To put an end to these reprehensible practices, the minister recommends the application of severe penalties. Voluntary mutilation and the production of disease by a soldier in himself for the sake of escaping his duty is to be punished as a case of refusal to obey or abandonment of a post of duty.

CANNED MEAT IN THE DIET OF THE ARMIES IN THE FIELD

M. A. Kling, doctor of science and director of the municipal laboratory of Paris, and M. G. Hinard, an engineer-chemist, who occupy two important positions in the Division des Conserves du camp retranché de Paris, have just published in the Revue scientifique a very interesting study on canned meats and their utilization in the rations of the armies in the field.

In the entrenched quarters of Paris, two procedures have been employed for the manufacture of canned beef. The first is the procedure well known under the name of Appert or Chevallier-Appert and used in times of peace for army rations. It consists essentially in "blanching" the meat, that is, in giving it a preliminary partial cooking before putting it in the cans. The liquor from this cooking is concentrated so that it jellies on being cooled and is put into the cans with the meat. This blanching is less for the purpose of cooking the meat than for its partial evaporation. The meat loses from 40 to 45 per cent. of water during

John Rollen Moore, M.D. American Medical College, Eclectic, St. Louis, 1888; aged 54; for many years a practitioner of Lapel, Ind.; a director of the Greenfield (Ind.) Banking Company and president of the Greenfield Ice and Fuel Company; died at his home in Greenfield, Ind., September 13, from heart disease.

William H. Krickbaum, M.D. University of Pennsylvania, Philadelphia, 1902; aged 37; a Fellow of the American Medical Association and a member of the staff of the Danville (Pa.) State Hospital for the Insane; died in the George F. Geisinger Memorial Hospital, Danville, Pa., September 21, from typhoid fever.

John Myrick Thompson, M.D. Jefferson Medical College, 1872; aged 64; of Ocala, Fla.; formerly a member of the Florida Medical Association; visiting physician and a member of the board of managers of the Marion Hospital, Ocala, Fla.; died in Jacksonville, Fla., about June 22, from heart disease.

Porter I. Mulholland, M.D. Toledo (Ohio) Medical College, 1902; aged 40; a Fellow of the American Medical Association; assistant surgeon Ohio Naval Militia and on duty on the training ship *Essex* during its cruise in August; died at his home in Toledo, Ohio, September 20, from typhoid fever.

Colin McDougall, M.D. Bellevue Medical College, 1878; aged 74; formerly a member of the Medical Society of the State of New York; for many years physician to the Actors' Fund; a member of the staff of the New York Nose, Throat and Lung Hospital; died at his home in New York, September 19.

John Merrick Bemis, M.D. University of Vermont, Burlington, 1893; aged 55; a member of the Massachusetts Medical Society; superintendent and physician in charge of Herbert Hall, Worcester, Mass.; well known as a neurologist; died at his home in Worcester, September 22, from nephritis.

David Hunt, M.D. Harvard Medical School, 1867; aged 70; formerly a practitioner of Boston and Worcester, Mass.; an authority on medical history, and a specialist on diseases of the eye and ear; died at the home of his daughter in Detroit, September 15, from cerebral hemorrhage.

John S. Wolff, M.D. Jefferson Medical College, 1853; aged 88; for more than sixty years a practitioner of the Shiloh section of Laurens County, S. C.; in 1892 and 1894 a member of the South Carolina Legislature; died at the home of his son in Laurens, S. C., September 18.

Elijah Andrew Covington, M.D. Medical College of the State of South Carolina, Charleston, 1868; aged 77; a Confederate veteran; for many years a druggist and hardware merchant of Wadesboro, N. C.; died at his home in Wadesboro, September 12, from acute gastritis.

Edward Alexander, M.D. University of Vienna, Austria, 1854; aged 85; for forty-five years a practitioner of El Paso; at one time contract surgeon in the Army at Fort Bliss and later United States quarantine officer; died at his home in El Paso, September 18.

James Porter Davis, M.D. Medical College of Georgia, Augusta, 1883; aged 65; a Fellow of the American Medical Association; formerly chairman of the Board of Health of Tennille, Ga.; died at his home in Riddleville, Ga., September 7.

John Dickson, M.D. University of Maryland, Baltimore, 1852; aged 84; for many years a practitioner of Baltimore, but for the last quarter of a century a resident of California; died at his home in San Francisco, September 15, from senile debility.

Simeon Dosson Taylor, M.D. Vanderbilt University, Nashville, Tenn., 1887; aged 53; a member of the Kentucky State Medical Association; a practitioner and druggist of Beaver Dam, Ky.; died at his home, August 2, from typhoid fever.

Arthur W. Parker, M.D. College of Physicians and Surgeons, Keokuk, Iowa, 1881; aged 61; died at his home in Essex, Iowa, September 6, from carcinoma of the stomach and liver.

Samuel Lafayette Weed, M.D. University of Alabama, Mobile, 1886; aged 56; of Helena, Ala.; died in an infirmary in Birmingham, Ala., September 9.

William A. Settle, M.D. University of Louisville, Ky., '77; aged 65; died at his home in Greensburg, Ky., September 14.

Correspondence

Sign for Distinguishing Gaseous Distention from Appendicitis

To the Editor:—I have on several occasions noted a sign which appears to be of value in differentiating between acute appendicitis and simple gaseous distention of the cecum associated with acute bowel fermentation. So far as I know the sign has never been described. It is elicited as follows:

Gentle pressure is brought to bear over the cecum, pressing in an upward direction. If the condition is simply gaseous distention, the patient will complain of pain in this region, but also complains of pain in left hypochondrium; pain disappears when the pressure is relieved. The explanation appears to be this: The enormous quantity of gas in the cecum is forced upward by the pressure, passing along the ascending and transverse colon, but is caught at the acute splenic flexure. The sharp impact of the gas here causes pain. This sign has on several occasions been of value to me and prevented operation in doubtful cases.

S. Salzman, M.D., Toledo, Ohio.

Emetin: A Warning

To the Editor:—Those using emetin solutions should be very careful not to get any in the eyes. This accident is followed by a very severe reaction. There is no pain at first, but in about eight hours there is an uncomfortable, "scratchy" feeling, intense photophobia and lacrimation, with conjunctival and some circumcorneal injection. Duration is about two days. To date I have seen two cases. A detailed report of these cases will be published later.

Julian B. Blue, M.D., Memphis, Tenn.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter *must* contain the writer's name and address, but these will be omitted, on request.

LUETIN TEST—DIONIN IN CATARACT

To the Editor:—1. Can you advise me regarding the reliability of the luetin test which is now being marketed commercially? Has any comparison been made between that and the Wassermann and Noguchi tests?

2. Can you express an opinion on the treatment of cataract by the use of dionin (ethyl-morphin hydrochlorid); either in the conjunctival sac or by subconjunctival injection, or by the use of any form of electric current? Is there any recent literature on these subjects?

E. B. J.

Answer.—1. The luetin test is described on page 334 of New and Nonofficial Remedies, 1915. Numerous references occur in the literature to comparisons of results with this test and with the Wassermann and the Noguchi modification of the Wassermann. The article in New and Nonofficial Remedies says:

> "Luetin is employed for the diagnosis of syphilis. It is of use in the examination of tertiary cases but rarely gives a positive reaction in the primary cases or in untreated secondary cases. In patients who are under treatment by mercury or salvarsan, the reaction is frequently positive even in cases which fail to give a positive Wassermann reaction."

2. The nonoperative treatment of cataract has occupied the attention of ophthalmologists from the earliest times, both before and since its pathology was understood. It is true that in some cases of genuine cataract the opacity has disappeared without treatment, and it is not uncommon to see the disappearance of diabetic striae and the occasional absorption of exudates between the fibrillae of the lens which have produced more or less cloudiness. Attempts have been made to cure this condition by the employment of various drugs, massage with various ointments, the use of galvanism, the subconjunctival injection of potassium iodid, dionin, mercury, etc. In cases of incipient senile cataract a number

of ophthalmologists have reported good results in delaying the development of opacities by the subconjunctival injection of potassium iodid combined with the use of dionin powder insufflated into the conjunctival sac. The great majority of cases of cataract, however, are progressive and show no improvement under any form of local treatment; when useful vision is lost a surgical operation is the only treatment. Volumes II and III of "The American [illegible] Ophthalmology" contain a complete summar[illegible] with bibliographic references to the most recent literature.

REFERENCES ON SOCIAL MEDICINE

To the Editor:—I am interested in the subject of social medicine. Please give me some data as to where I can obtain literature on this subject.

W. L. Albin, M.D., University Place, Neb.

BINET-SIMON TEST—HEALY TEST—D'ESPINE SIGN—KORANYI SIGN—EWART SIGN

To the Editor:—Please describe for me: (1) the Binet-Simon test of mentality; (2) the Healy psychologic test; (3) the D'Espine sign; (4) the Korányi sign, and (5) Ewart's sign.

C. R. Byers, M.D., Bay City, Texas.

Answer.—1. The inquiry regarding the Binet-Simon test was answered in The Journal, Jan. 13, 1912. This series of tests is published in a pamphlet by A. Binet and T. Simon, entitled "A Method of Measuring the Development of the Intelligence of Young Children," published by the Courier Company, Lincoln, Ill.; price, $1. A list of the recent literature on this subject was published in The Journal, Jan. 10, 1914. The series of questions and problems in this test are too extensive for publication in this department.

2. The Healy psychologic test is described in a monograph by William Healy and Grace Fernald, published by the Psychologic Review Publishing Company, Princeton University, Princeton, N. J.

2. In 1907, D'Espine (*Bull. de l'Acad. de méd.*, Paris, 1907, lxii, 167) drew attention to a sign which he considered diagnostic of enlargements of the bronchial glands. He stated that in young children the whispered voice normally ceases at the level of the seventh cervical spine posteriorly. When, however, there is enlargement of the lymph nodes and the patient whispers "three thirty three," or similar numbers, bronchophony is heard over the upper thoracic spine as well. A recent study of this sign has been made by H. F. Stoll ("The Diagnostic Significance of D'Espine's Sign," *Am. Jour. Dis*[illegible] September, 1915, p. 183.

4. Korányi's sign is the same as Grocco's sign. In a medium-sized pleural effusion an S-shaped dulness can be determined as the upper limit of the effusion. The line begins rather low down at the spine, curves upward and obliquely across the chest into the axilla, then descends to the sternum. Movable dulness may be determined with changes in the patient's position. A triangular area of dulness may be found on the opposite side of the effusion. The base is at the level of the lower border of the lung and the apex about the height of the upper level of dulness. This latter finding is known as Grocco's sign. The presence of a normal triangular area of paravertebral dulness diminishes the diagnostic value of this sign. Reference may be made to Musser, "Medical Diagnosis," p. 604, and F. Smithies; (*Arch. Diag.*, April, 1912; Abst., The Journal, June 22, 1912).

5. Ewart's sign is of importance in the diagnosis of pericardial effusion. It is the prominence of the sternal end of the left first rib with elevation of the head of the clavicle.

ULTRAVIOLET RAYS AND INCANDESCENT ELECTRIC LIGHTS IN INFLAMMATORY CONDITIONS

To the Editor:—1. What candle power of incandescent electric lights produces the most ultraviolet rays?

2. What is the value of the ultraviolet rays so produced, for the treatment of acute inflammations like cellulitis, and for deep-seated chronic inflammations?

C. D. E., Oregon.

Answer.—1. The incandescent electric light produces few ultraviolet rays. Its spectrum contains not nearly so many ultraviolet rays as the arc light. The greatest quantity of ultraviolet rays is produced by incandescent mercury vapor in the mercury vapor lamps of the Cooper-Hewitt type. In order to get a large number of these rays for therapeutic purposes these mercury lamps must be made of quartz, which permits the passage of nearly all violet and ultraviolet rays. Glass absorbs a great quantity of these rays.

2. Ultraviolet rays penetrate tissue only slightly—not more than one-half inch—when the tissues are compressed so that they are almost bloodless. They scarcely penetrate blood at all. It is difficult to see how ultraviolet rays can be of any therapeutic value in treating any sort of process not near the surface of the skin. In the so-called ultraviolet lamps in which the source of light is an incandescent electric light, usually backed by a parabolic reflector, all the effects that can be obtained from light are on the surface. Because of the absence of ultraviolet rays in this light, it is probable that its physiologic effect is inappreciable; whatever therapeutic powers such lamps possess are perhaps due to the heat given off by them, which, in the case of incandescent lights, is considerable.

MORTALITY FROM RATTLESNAKE BITES

To the Editor:—Will you kindly inform me regarding the relative mortality from rattlesnake bites?

R. N. Pierson, Stamford, Conn.

Answer.—Prentiss Willson, in a very complete article on the general subject, which includes a summary of the literature (Snake Poisoning in the United States, *Arch. Int. Med.*, June, 1908, p. 516), says:

> "The mortality from the bites of American serpents has never been satisfactorily determined. Mitchell, in 1860, stated that in 57 cases of rattlesnake bite mentioned in the literature, five patients died. This would represent a mortality of 8.7 per cent. Elzey, whose opinion is often quoted, merely estimated that in 15 per cent. of cases of rattlesnake bite in adults, the patients would die, if left untreated. Barringer stated his belief that the mortality from rattlesnake bite would not exceed 10 per cent. and from copperhead bite 1 per cent. The mortality from water moccasin bite, he thought, would fall below even this last figure. *There were 78 fatal cases in the total of 740 which I have* collected, a mortality of 10.5 per cent. This figure represents the mortality of all species combined, and in my opinion may be accepted as representing with considerable accuracy the actual mortality attending snake bite in the United States, the number of cases on which it is based being considerable, and having been collected from sufficiently varied sources. As tending to prove the accuracy of this rate, it may be stated that the mortality rates for cases collected from the literature and from various private sources were, respectively, 10.2 per cent. and 10.7 per cent., a variation of only 0.5 per cent. The mortality rate for the different species will be given later in considering the effect of species on the prognosis."

In a tabulation of 624 cases of snakebite, in which the species were known more or less definitely, Willson found a mortality rate for all rattlesnake cases of 11.7 per cent. This he considers approximately correct.

Illinois June Report

Dr. C. St. Clair Drake, secretary of the Illinois State Board of Health, reports the written examination held at Chicago, June 24-26, 1915. The total number of subjects examined in was 10; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 200, of whom 177 passed and 23 failed, including 4 candidates who did not complete the examination. The following colleges were represented:

College	PASSED Year Grad.	Per Cent.
Bennett Medical College	(1913) (1914, 3) (1915, 21)	25
Chicago College of Med. and Surg.	(1914, 2) (1915, 26)	28
Hahnemann Med. Coll. and Hosp., Chicago	(1914, 2) (1915, 9)	11
Jenner Medical College	(1915)	11
Northwestern University	(1914) (1915, 12)	13
Rush Medical College	(1914) (1915, 29)	30
University of Illinois	(1912) (1915, 45)	46
University of Louisville	(1910) (1915)	2
University of Maryland	(1915)	1
Harvard University	(1912) (1915)	2
University of Minnesota	(1893)	1
St. Louis University	(1915)	2
Washington University	(1915)	1
John A. Creighton Medical College	(1911)	1
Meharry Medical College	(1915)	2
Catholic University, Louvain	(1895)	1
FAILED		
Bennett Medical College	(1914, 3) (1915, 3)	6
Chicago College of Med. and Surg.	(1914, 2) (1915, 3)	5
Chicago Hosp. Coll. of Medicine	(1915)	1
Hahnemann Med. Coll. and Hosp., Chicago	(1915)	2
National Med. Univ., Chicago	(1909)	1
University of Illinois	(1913) (1915)	2
National Univ. of Arts and Sciences	(1914)	1
University of Pennsylvania	(1896)	1

Alaska July Report

Dr. H. C. DeVighne, secretary of the Alaska Board of Medical Examiners, reports the written examination held at Juneau, Alaska, July 6, 1915. The total number of subjects examined in was 12; total number of questions asked, 120; percentage required to pass, 75. The total number of candidates examined was 6, all of whom passed. The following colleges were represented:

College	PASSED Year Grad.	Per Cent.
College of P. and S., San Francisco	(1909)	76.5
University of Georgia	(1912)	80
Rush Medical College	(1889)	75
State Univ. of Iowa, College of Medicine	(1886)	75.8
University of Mich. Medical School	(1900)	77
Marion-Sims College of Medicine	(1898)	80.9

Arizona July Report

Dr. John Wix Thomas, secretary of the Board of Medical Examiners of Arizona, reports the written examination held at Phoenix, July 6-7, 1915. The total number of subjects examined in was 10; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 9, of whom 5 passed, including 2 osteopaths, and 4 failed, including 2 osteopaths. The following colleges were represented:

College	PASSED Year Grad.	Per Cent.
University of Southern California	(1899)	78
Tufts College Medical School	(1906)	75.1
Medico-Chirurgical College of Phila	(1902)	76.8
FAILED		
College of P. and S., San Francisco	(1913)	71.2
Vanderbilt University	(1914)	72.2

Book Notices

A MANUAL FOR HEALTH OFFICERS. By J. Scott MacNutt, A.B., S.B. Foreword by William T. Sedgwick, Professor of Biology and Public Health in the Massachusetts Institute of Technology. Cloth. Price, $3 net. Pp. 660, with illustrations. New York: John Wiley & Sons, 1915.

The increasing number of workers in the public health field, both physicians and laymen, has created a distinct demand for a compact, practical, up-to-date reference book for health officers. The fact that Mr. MacNutt's training was secured, not in a medical school, but in the Massachusetts Institute of Technology, has naturally influenced both his point of view and his method of treatment. The publication of such a volume by a nonmedical man is conclusive evidence of the way in which the entire public health field is widening. The book is divided into two main parts, the first dealing with health authorities, their organization and powers and the second with public health administration. Under the first head, local, state and federal health authorities and their functions are discussed; also unofficial organizations. In the section on public health administration, the greater part of the space is naturally devoted to the discussion of communicable diseases and methods for their prevention. Child hygiene, food sanitation, water supply and housing are also discussed. While the book is one of the best practical manuals for health officers that has appeared recently and while its perusal will be of marked benefit and interest to every one interested in public health administration, the lack of medical training on the part of the writer is evident throughout. Equally evident is the lack of familiarity with the large amount of material on public health questions to be found in the leading medical journals, most of the periodical references being to one or two journals. It is also noticeable that most of the material and information utilized in the volume is drawn from a few of the eastern states. Mr. MacNutt's book is worthy of careful study, but it is unfortunately limited in both its material and its point of view.

A TEXT-BOOK OF MEDICAL JURISPRUDENCE AND TOXICOLOGY. By John Glaister, M.D., D.P.H., F.R.S.E., Professor of Forensic Medicine in the University of Glasgow. Third Edition. Cloth. Price, $5 net. Pp. 857, with 138 illustrations. New York: William Wood & Co., 1915.

Dr. Glaister's work is now issued in two volumes, one on "Medical Jurisprudence and Toxicology" and the other on "Public Health." Since its last appearance, the book has been thoroughly revised and rearranged and a more complete and detailed index prepared. While it is naturally of greater value to the English reader because it applies to legal procedure in that country, yet the breadth of Dr. Glaister's experience and the large amount of data which he has collected must make this book of interest to all students of medical jurisprudence. Especially interesting are the chapters on "Personal Identity," "Finger Prints," "the Identification of the Dead," "Gunshot Wounds" and "Deaths by Lightning and Electricity." Poisons and poisoning are exhaustively discussed. The chapter on "Wounds and Their Medicolegal Relations" is well illustrated and illuminated by copious extracts from case reports. The microscopic and chemical identification of blood and other body fluids is also authoritatively considered. The third edition of this work is a marked improvement over the preceding editions.

THE EARLY DIAGNOSIS OF HEART FAILURE AND OTHER ESSAYS ON THE HEART AND CIRCULATION. By T. Stacey Wilson, M.D., F.R.C.P., B.Sc., Senior Physician, General Hospital, Birmingham. Cloth. Price, $4.50 net. Pp. 617, with illustrations. New York: William Wood & Co., 1915.

There are in this book several essays dealing with the heart and circulation. Most of them treat of heart failure. Had Wilson selected a few of his newer ideas, such as the "high diaphragm" or "diminution in the area of liver dul[illegible]s" as signs of myocardial weakness, or the "distensibility [illegible] heart wa[illegible]" and emphasized these, omitting many of [illegible] physical examination of the heart and [illegible] his argument would have gained in effectiveness from concentration. As it is, even with his summaries and wearisome repetition, it is hard at times to make out what he is driving at. There is much that is suggestive in the book and it shows painstaking and conscientious study of an important subject along somewhat new lines. It is not always recognized that the heart that fails may in the one case enlarge, while in the other instance the lack of distensibility of the heart wall causes the organ to remain small. These and other points are well worth consideration by practitioners, for whom the book is primarily intended.

URGENT SYMPTOMS IN MEDICAL PRACTICE. By Robert Saundby, M.D., Lieutenant-Colonel, R.A.M.C. Cloth. Price, $2.10 net. Pp. 437. New York: Longmans, Green & Co., 1915.

Saundby has arranged alphabetically an indiscriminate list of subjects, covering not only what the title indicates, but other fields of medicine as well. He includes not only symptoms but many diseases and several pathologic tests. In the selection of the subjects covered there seems to be neither rhyme nor reason. No subject is covered completely. Such subjects as acne, alopecia, genital spots, immunity, keloid or paralysis agitans can hardly be listed as urgent. In the discussion of treatment the author is exceptionally free in his references to proprietaries, some ethical and others not so good. As a reference work to the things in it the book has a certain value.

Miscellany

"The Brides in a Bath" Case

The most sensational murder case in England since the Crippen trial has terminated in the conviction of George Joseph Smith, aged 43. The case is extraordinary in the annals of criminal jurisprudence, and presents several points of medicolegal interest. The prisoner contracted bigamous marriages with three women who soon afterward were found dead in a bath in very similar circumstances. The physicians who were called in, while rightly coming to the conclusion that death was due to drowning, were hoodwinked as to the cause, and thought that the death was accidental. The prisoner, a short time before each death, cunningly took the women to the physicians with the complaint of headache or fits, so as to facilitate the belief that death was due to natural causes. The deaths took place in lodging houses. After them he managed to slip out and return after buying food and pretended that he had just found the woman dead. The theory of the prosecution was that he pulled up the legs in such a position that the head would be submerged and the woman incapable of successfully struggling or screaming. In one case the physician thought that the woman had an epileptic seizure while in the bath and was thus drowned, but there was no proof, merely the prisoner's allegation, that she suffered from epilepsy. In another case the physician thought that the woman fainted from the heat of the bath and was drowned. The evidence of Dr. Spilsbury, medicolegal expert, was important. In the case of two of the baths he thought it was impossible for the head to be accidentally submerged so as to cause drowning. In one, while the woman's height was 5 feet 8 inches, the bath measured only 5 feet at the top, and 3 feet 8 inches at the bottom. In one case a piece of soap was found grasped in the hand after death. Dr. Spilsbury said that if the woman had fainted, the muscles would have been relaxed and the soap would have fallen out. If she had had a fit, it would probably have been retained in the first stage, but in the second or clonic stage would more likely have fallen out, and certainly would have fallen out in the third stage of exhaustion. He concluded, therefore, that consciousness was not lost before death, but that death was due to submersion, and that the contraction of the muscles passed into rigor mortis, causing the soap to be retained. It was never even proved that the prisoner was in the bath room at the time of death, and therefore the evidence was entirely circumstantial. The judge pointed out the following series of coincidences in the circumstances of the three deaths, which were too many to be regarded as accidental: 1. In each case there was a death in a bath, and in each case the prisoner had moved to that bath room or fitted it up within a week before the death. 2. In each case the bath room in which the death took place was unlocked, so that the prisoner could go into it, although in two cases it was in a strange house and other lodgers might enter. 3. In each case the dead woman made her will in favor of the prisoner within a week before her death. 4. In two of the cases, the dead woman insured her life within ten days before her death; in the third case there was no insurance because there was considerable property which would pass on death. 5. In each case, all the debts due to the dead woman and all savings bank accounts had been realized just before death. 6. In each case, two or three days before the death the woman was taken to a strange physician in a strange place complaining of headache, and that physician was called in after death. 7. In each case, a letter was written to the woman's relatives a day before her death. 8. In each case, the prisoner had gone out to buy food when the woman was found drowned. 9. In each case, the prisoner found her, left her in the water until some one had seen her, and did not get rid of the water without permission. 10. In each case, it was a bigamous marriage. 11. In each case, he benefited more by death than by life. 12. In each case, he buried the woman as quickly as possible. It is to be noted that the evidence in any one of the three cases was so slight that the prisoner could scarcely have been put on his trial. Indeed, no suspicions were even aroused until the third case. Then the remarkable series of coincidences given above proved fatal to the prisoner.

The Pennsylvania Department of Health Exhibit at the Panama-Pacific International Exposition

The mammoth exhibit of the commonwealth of Pennsylvania is a credit to that state and to its commissioner of health, Dr. Samuel G. Dixon. The exhibit is surrounded on all sides with white pennants, each bearing an attractive green keystone; from the center beam and at each end are draped the Stars and Stripes, side by side with the blue silk flag of Pennsylvania. Almost the first thing that arrests the eye is the sentiment written by Dr. Dixon: "The varied industries on which we depend for our comfort, the wealth which enables us to enjoy them, and the arts of civilization which adorn and diversify our lives are but the fruitage of the tree whose root is health." The exhibit graphically portrays the activities of the department, roughly divided into three separate sections: school hygiene, typhoid fever and sanitary engineering, and the tuberculosis work of the department.

In the section on school hygiene are pictures showing the inspection of rural schoolchildren, of which Pennsylvania inspects approximately 400,000 a year. Statistics give the percentage of defects found under vision, hearing, teeth, nose and throat, skin diseases, nervous diseases and tuberculosis in all its forms. It is perhaps the only state in the union which has undertaken medical and sanitary inspection of rural schools on such a vast scale, under state supervision. The dangers of the common towel are made clear by life-sized wax models of pupils, the evolution of the sanitary drinking cup and fountain is illustrated, and good and bad seating facilities in schools are shown by life-sized wax models of boys and girls in actual seats placed at adjustable desks. Transparencies depict the progress and evolution of schoolhouses, from the old insanitary, unlighted country school to the modern, pleasant, well-lighted building. A model of an artistic school building and grounds and its screened outhouses suggests the ideal.

The division devoted to typhoid fever and sanitary engineering covers a large area. There are models of a complete sewage-disposal plant, and of towns and cities in which epidemics of typhoid fever occur. The manner and the source of infection are shown by miniature houses and the depiction of streams and leaky flumes, overflowing vaults, carelessness at dairy farms, inadequate care of sewage from trains and boats, and the pollution of streams by dead animals and outhouses.

No part of the exhibit has attracted more attention than that which portrays by models, pictures or transparencies the work of Pennsylvania for the care of consumptives, and the work that is going to educate the people for its prevention. Models are shown of Pennsylvania's three large sanatoriums which can accommodate approximately 2,000 patients afflicted with this disease. Types of cottages used at the "camp" and occupied by the patients in the incipient stages are reproduced with every detail, even to the miniature bed, bedclothes and wash basin in each room. The work of the visiting or dispensary nurse is shown by transparencies. The work of the new Bureau of Housing is also indicated, as well as that by the bacteriologic and pathologic laboratory, where all specimens are sent for examination.

Dr. Dixon and the exhibit were each awarded a gold medal.

The Undiagnosable

"It is one of the commonplaces of worldly wisdom not to try to educate the public. The business man will make his boldest bid to supply an already existent demand, or to create a demand for something that he wants to sell; but he is never supposed to succeed if he spends his time and money in getting the world at large to do what it ought, instead of allowing it to do what it often vainly imagines is to its own advantage. The medical profession can, to a certain extent, contradict this assertion; we are, spasmodically and vicariously, it is true, making the people at large put up with methods that are clearly not so satisfying to them as those that they replace, and not only that, but we are persuading people actually to prefer the more uninviting system. Nothing could have been more comforting to the world of sick in general than the old belief in the infallibility of the physician. To know for an absolute certainity that the whole case lay bare before one's medical adviser, as if he were gifted with a diagnostic combination of the Roentgen ray and clairvoyance which showed him all the iniquities of the pecant organism like an open book, must have been a boon that contributed not a little to the peace of mind, and so indirectly, to the more rapid recovery of the patient. But it was not true.

"It may be argued that that was but a detail. If the application of the false is a suitable therapeutic agent, why should we go out of our way to avoid it when in addition it offers all the additional advantages of being the path of least resistance? We may tell ourselves that if our patients do not suffer by a little undue dogmatism and unjustifiable confidence on our part, we have done them no harm, and have at any rate, sustained our own reputation. We forget the harm we do to ourselves. Slipshod untruth is unscientific. We need not refer to its ethics. It is in the wrong spirit. Its practice makes us only too ready to repeat it out of sheer laziness. And the next thing is that we find ourselves dividing cases into those of M. F. S., Mist. Carm., Mist. Expect. Sed., and so on, which is obviously fatal to anything but a commercial success in the practice of medicine. It is to our credit that we have educated so many of our patients to look on us as fallible, as people like themselves, to whom mistakes are possible and who do not know everything. Such a spirit is the right one if we wish for the real advancement of medicine, and, as a sop for Cerberus, it pays in the long run."—*Medical Press and Circular.*

The Engineer in Public Health Work.—There are certain good reasons for the evolution [the engineer in public health work], for health work no longer stands on the basis of medicine alone. Light, ventilation and humidity come into the problem of health; construction is most important, and in these matters the value of the engineer is obvious. Health administration never can be independent of medical skill and practice—medicine and engineering must go hand in hand.—*American Journal of Public Health.*

Virginia State Medical Society, Richmond, Oct. 26-28.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA

Sixty-Fifth Annual Meeting, held in Philadelphia, Sept. 20-25, 1915

The President, Dr. Edward B. Heckel, Pittsburgh, in the Chair

Civic Responsibility of the Physician and the Medical Society

Dr. John B. McAlister, Harrisburg: Some of the most vital problems for thought are: (1) Standardization of the profession throughout the country. May we live to see the day when a licensed doctor in Oklahoma is a licensed doctor in Pennsylvania. (2) Medical legislation in Pennsylvania. Our legislative committee needs our wisest judgment and conscientious cooperation. The establishment of a board of regents similar to the New York Board of Regents would solve the problem of the constant struggle to protect our own standards, protect the public against fraud and incompetency, relieve us of the reproach of bigotry and selfishness and prevent the multiplicity of examining boards. (3) Preventive medicine calls loudly for a National Health Department in the Federal Government. (4) Cancer and tuberculosis which are preventable at some stage. (5) The doctor and the newspaper. The newspaper is more powerful than all the guns of all the armies in the world. The doctor and the press should join forces for the public good. The press is of inestimable service in educating the public in health, hygiene and preventive medicine, and in influencing legislatures.

Report of the Subcommittee on Cancer for 1915

Dr. Jonathan M. Wainwright: This society was the first organization in this country to make any systematic effort to attack this problem. Our first effort was to induce every medical college professor interested in a subject approaching cancer to impress on his students the fundamental points of the cancer campaign. We hope to induce our examining boards to insist on a proper knowledge of cancer. We have tried to induce every nurse's training school in the state to have their nurses properly instructed regarding the disease. Perhaps the most efficient plan by which the society has worked has been through our county societies. In June thirty-eight counties held meetings devoted to this subject. We believe that much the most important and efficient single effort ever made in this country and perhaps abroad in the attack on cancer has been the effort to have our medical journals devote a major part of their July issue to the cancer campaign. Sixty-five journals responded. The American Society for the Control of Cancer is cooperating with our society.

Scopolamin-Morphin Anesthesia in Obstetrics

Dr. James R. Freeland, Pittsburgh: The literature appearing in association with this subject in the last fifteen months is to be classed largely as advertising matter. Scopolamin should be considered simply as a useful sedative in selected cases. This attitude is probably responsible for our good results. Complete amnesia should not be regarded as the main object. The attitude of the physician toward patients demanding "twilight sleep" should be that of reserving the right to choose the anesthetic just as the surgeon does. The demand for painless labor denotes an unhealthy mental attitude.

DISCUSSION

Dr. Barton Cooke Hirst, Philadelphia: In a series of cases I find the disadvantages of this method to be—if there is given enough scopolamin and morphia to produce indifference to pain—prolongation of labor, tendency to atony of the uterus with hemorrhage and an increased proportion of apneic babies that cannot be revived. If one tries to escape these disadvantages by following the latest methods of giving minimum doses of the two drugs, the disadvantages disappear but the relief afforded is scarcely noticeable, in my experience. However, the advantages of this method are not to be ignored, and I have found it useful in primiparas of a neurotic type, apt to have a long painful labor. Here I use it not to relieve pain so much as for psychologic effect, which we cannot afford to ignore. I employ all the accessories, the darkened room and the banishment of everyone but a trained nurse and the doctor. It is not fair to take a negative stand in the criticism of any method unless some alternative is proposed. We should earnestly endeavor to preach a proper solution of this subject. I am at present making some experiments with cannabis indica as a drug which may relieve the pains of childbirth without disadvantage to mother or child.

Dr. Daniel Longaker, Philadelphia: The full benefit of scopolamin is obtained only when we secure complete amnesia. Every woman should be transferred to the specially appointed hospital for her confinement, regardless of the method of delivery. I agree with Dr. Freeland that the apnea is due to the morphia. There are certain cases in which neither scopolamin nor morphin should be used.

Dr. James R. Freeland: I am sorry I cannot join the enthusiasts for the use of scopolamin. My first objection is the name, "twilight sleep." It is a trade name, and has no place in the practice of medicine. The matter of suggestion is harmful to the patients and a certain proportion will come later into the hands of the neurologist.

Some Criteria Underlying Prognosis in Certain Forms of Cardiac Insufficiency

Dr. James E. Talley: The average patient of middle life with symptoms suggesting beginning cardiac insufficiency will probably have either (1) primary chronic endocardial or myocardial disease, usually rheumatic; (2) primary endocardial or myocardial disease with secondary nephritis; (3) primary renal disease with a secondary myocardial and vascular disease; (4) primary arterial or arteriocapillary sclerosis with secondary cardiac and renal disease; (5) syphilitic cardiovascular disease. Omitting Groups 1 and 5 we have three groups of cardiorenal and cardiovascular disease, of special interest because of their frequency, association with pathologic elevation of blood pressure and because their study has tended away from the conception of renal disease being solely responsible for hypertension, and toward the renewal of the old conception of primary arteriolarcapillary fibrosis. Myocardial weakness as expressed by early dyspnea foretells a death by cardiac insufficiency for one half of such patients. Extreme dyspnea may be associated with pulmonary edema which is lethal in one or a few attacks. Anginoid pain forecasts that one third of the patients will succumb in an acute anginal attack; the remainder to cardiac failure. The underlying criteria in prognosis are the information derived from symptoms and objective signs. The symptoms are many and vary as the heart or renal element predominates. Periodic early morning headache means a uremic death for a large number; an apoplectic death for a somewhat less number. Nocturnal polyuria points to a uremic death. Hypertension accompanies all three groups. Although all three groups are doomed, the one with the vastly impaired elimination is doomed to a renal death and probably earlier than the other two. Dr. Paul D. White has shown pulsus alternans to be much more common than we have thought. In cardiac, vascular, and renal patients the mode of death is given and the expectancy of life is furnished by the same statistics. From the onset of the first symptoms one half will succumb during the first five years; one quarter between five and ten years, and one quarter will be living after ten years.

DISCUSSION

Dr. Joseph Sailer, Philadelphia: The importance of the prognosis in cardiovascular disease is due largely to the fact that, although the conditions are incurable, much can be accomplished by therapeutic measures for the comfort of the patient and the prolongation of life. Differential diagnosis here is in degree rather than in the kind of the disease, and in this differential diagnosis of degree Dr. Talley has properly laid stress on blood pressure, colorimetric tests of the functional capacity of the kidneys and graphic methods of recording the heart action. These methods, however, are not absolute. The increase or decrease in the functional capacity of the kidneys, the rise or fall of arterial tension and possibly the modification of the heart tracing are more significant of the probable course of the case than any single observation.

Dr. H. B. Allyn, Philadelphia: The cause of the disease has much to do with the prognosis. Lesions resulting from an acute infection often remain quiescent for many years and the patient is not much worse. I have seen within a few days a patient who was left with aortic insufficiency from scarlet fever when 3 years old and who is now approaching 50. Her heart has needed little attention for fifteen years. On the other hand, when the lesion is a myocardial degeneration, the prognosis is much worse. Dyspnea, its degree and the readiness with which it is induced, is often of more value in prognosis than any physical sign.

Dr. H. A. Hare, Philadelphia: The more experience one has with cases of cardiovascular disease the more cautious is he in prognosis. While pulsus alternans is of grave import it is not unusual to see a patient with this symptom live several years. In reaching a prognosis in cardiac disease we must study the patient as a whole and not be content with examinations of the heart, even if these examinations are made with instruments of precision.

The Heart of the Athlete; Its Prospect and Protection

Dr. Robert N. Willson, Philadelphia: Two vital questions immediately involved in a study of the wisdom or physical unprofitableness of college and schoolboy competitive athletics are: (1) the ultimate (postgraduation) result of public competitive athletics on the physical health and lives of the participants; (2) the possibility of determining the genuine physical integrity of the proposed participant or his lack of the same, especially with respect to his heart. In recent years there have been many deaths among former athletes. I know of not one instance of recovery from a major infectious disease in an athlete, except in the typhoid epidemic at Easton. Here a number of undergraduates, presumably not yet shorn of their resisting forces, made a successful fight and recovered. We must remember that the normal heart will not tolerate repeated insults sustained in the strain of training and final competition without the loss of recuperative power. Latent athletic injuries would seem to explain the tendency of the strong and robust to die, while the less powerful win out against infectious disease. A still more radical evil is the encouragement offered by college and university to the schoolboy to emulate his college brother in competitive athletics. I stop short of advising against active competition as the Germans have. I am simply pointing to sign boards written in bold letters. Trainers should be taught just what the collapse of today means in the future of the athlete. Some day the college authorities must of necessity conclude that no form of athletic event is sane that demands of the participants the semiconscious state of heart exhaustion at its conclusion.

DISCUSSION

Dr. N. A. Stauffer: I believe in competitive sports for the same reason that I favor competition in other professions. All of the University of Pennsylvania football team are in excellent health, and records of athletes compiled by other observers do not bear out the statement that competitive sports are harmful, except to the unprepared.

Dr. Albert E. Roussel: Physicians should appreciate the value of graduated exercise throughout life, but exercise should be under supervision in selected cases.

Dr. R. N. Willson: I am not opposed to competiti athletics if they can be rendered sane. The point raised what will the athlete's heart do in the presence of systemi especially infectious, disease? I believe it is time to saf guard the hearts and vessels and lives of our boys.

Chronic Arthritis

Dr. Thomas McCrae: The etiologic factor in the great majority of cases of chronic arthritis is infection somewhere, and a knowledge of the cause is an important element in treatment. As the process is often progressive, it is the more essential to recognize this and endeavor to remove the cause before serious damage is done. This involves a thorough search for the possible source of infection and proper treatment if found. The effort to apply this etiologic therapy should be distinguished from measures which are merely symptomatic or those directed to improve the condition of joints already damaged.

DISCUSSION

Dr. A. P. Hirsh: The terms "rheumatoid arthritis" and "chronic rheumatism" should be named only to be discarded. A tentative nosology is now possible for chronic arthritic disease being based on the researches of Dr. McCrae and others in this field. Three factors involved in the definite treatment method of one group of joint infections wrongly classed "deforming arthritis" are: (1) removal of the original source of infection; (2) persistent local applications over each affected joint until all possible removable deposit is gone; (3) a systematic effort to correct the patient's general metabolism. Removal of the causative infection implies an exhaustive differential diagnosis. It is to the local treatment methods that attention is especially directed, the most efficient of which is the high pressure, small volume and low frequency static wave current sent through 22-gage flexible metal plates closely fitting the involved joints. The static indirect sparks are also applied between these joints. Of the several modalities no single one will suffice but their intelligent combination will bring success in the treatment of that opprobrium of our calling, deforming arthritis.

The Tertiary Manifestations of Syphilis as Seen in a General Medical Ward

Dr. John H. Musser, Jr.: The study is based on the results of the Wassermann test on every case of chronic disease coming into the men's medical service at the Presbyterian Hospital in the last four months, excluding the frank pneumonia and typhoid fever cases, and necessarily those dying, or leaving the ward before there was time for the test. It was found that one fifth of patients with chronic disease had syphilis. The following conclusions may be drawn: 1. A large percentage of cases of chronic disease is dependent on a syphilitic infection. 2. It is impossible always to detect such cases of syphilitic infection without a Wassermann reaction. 3. Owing to the importance of diagnosing such cases which show syphilitic infection, a Wassermann test of the blood serum should be made in every case of chronic disease admitted to a general medical ward.

Dr. Joseph Sailer: That many forms of chronic disease are dependent on a syphilitic infection which does not manifest itself in the usual way is the experience of all of us. Of two such patients both physicians, one suffered merely from malnutrition and indefinite digestive disturbance for which there was no adequate explanation. The Wassermann was positive. Two weeks after the first injection of salvarsan he gained ten pounds and has since remained well. The other physician suffered merely from an irritative dry cough of the most persistent character. He was the father of three healthy children. There were none of the ordinary manifestations of syphilis. A positive Wassermann suggested the use of salvarsan and the cough stopped almost immediately after the first intravenous injection. Assuming that only 10 per cent. of the population suffers from syphilis, which, based on our laboratory reports is a modest number, at least 9,000,000 people suffer from it in the United States. It is fair to conclude that in the majority the manifestations are so obscure that there is no suspicion of its existence.

4 *Origin of Blood and Vascular Endothelium in Embryos without Circulation of Blood and in Normal Embryo. C. R. Stockard, New York.

4. **Origin of Blood and Endothelium.**—According to Stockard in most embryos the earliest blood cell formation occurs in the yolk-sac blood islands. The cells in these islands continue to divide until they become surrounded by endothelium, then the yolk-sac blood islands lose their hematopoietic function and become a vascular net through which the blood circulates. The liver now takes up the rôle of harboring dividing blood cells within its tissue spaces, when these spaces become vascularized by endothelium; here again the blood cells no longer multiply but merely circulate. Finally, in the mammalian embryo, one organ after another ceases to offer the necessary harbor for dividing blood cells, until the red bone marrow is the only tissue presenting the proper relationship of spaces and vessels, and here alone the erythropoietic function exists to supply the red blood cells for the entire body circulation. The red blood corpuscles are always produced so as to be delivered into the vessels and thus soon occupy an intravascular position, while the white blood cells arise and remain for some time among the mesenchymal tissue cells in an extravascular position. Lymphocytes and leukocytes along with the invertebrate amebocytes are all generalized, more or less primitive, wandering cells and are almost universally distributed throughout the metazoa.

Erythrocytes are highly specialized cells with a peculiar oxygen carrying function due to their hemoglobin content. In contrast to the universal distribution of the leukocytes the erythrocytes are only found in the vertebrate phylum, except for a few cases existing in some of the higher invertebrate groups. Yet even in these particular cases the oxygen-carrying blood cell never presents the typically uniform appearance of the vertebrate erythrocyte. The facts presented seem to indicate that vascular endothelium, erythrocytes and leukocytes, although all arise from mesenchyme, are really polyphyletic in origin; that is, each has a different mesenchymal anlage. To make the meaning absolutely clear, Stockard considers the origin of the liver and pancreas cells as parallel, as both arise from the endoderm but each is formed by a distinctly different endodermal anlage, and if one of these two anlagen is destroyed the other is powerless to replace its product.

5. **Gastro-Enterostomy.**—The largest proportion of cases in the series studied by Finney and Friedenwald in which gastro-enterostomy was performed occurred between the thirtieth and sixtieth years, while the largest proportion of cases in which pyloroplasty was performed occurred between the thirty-fifth and fiftieth years. The duration of the symptoms in the gastro-enterostomy cases varied from one month to nineteen years, while the duration of symptoms in the pyloroplasty cases varied between one and one-half months to twenty-five years. In the gastro-enterostomy cases the symptoms appeared in the following proportions; pain in 90 per cent.; vomiting in 65 per cent.; hematemesis in 23 per cent.; melena in 44 per cent.; retention in 36 per cent.; while in the pyloroplasty cases pain was present in 92 per cent. of cases; vomiting in 64 per cent.; hematemesis in 21 per cent.; melena in 46 per cent.; retention in 42 per cent. In the gastro-enterostomy series the ulcer cases are arranged as follows: There are 46 cases of gastric ulcer, 38 duodenal ulcers. In the pyloroplasty cases there were 55 cases of gastric ulcer and 32 duodenal ulcers. In 67 of the gastro-enterostomy patients operated on for obstruction 44 were due to gastric ulcer, 14 to duodenal ulcer, and 9 to adhesions, while pyloroplasty was performed for obstruction in 64 instances; for gastric ulcer in 51, for duodenal ulcer in 7, and in 6 for adhesions.

In the gastro-enterostomy cases secondary operations were performed in four instances to correct immediate difficulties, while in the pyloroplasty cases secondary operations were required in the same number of instances for a similar purpose. After gastro-enterostomy satisfactory results were secured in 82 per cent. of cases, and unsatisfactory in 18 per cent., while pyloroplasty was immediately successful in 90 per cent. of cases and unsatisfactory in 10 per cent. There were seven deaths, following immediately on the operation of gastro-enterostomy, while but five deaths followed pyloroplasty. Of the seventy-seven cases of gastro-enterostomy followed during the first year of the operation the results were satisfactory in 84.4 per cent. and unsatisfactory in 15.6 per cent., while of the eighty-two cases of pyloroplasty the results were entirely satisfactory in 93.9 per cent., and unsatisfactory in 6.1 per cent. Of the gastro-enterostomy cases, numbering seventy-four, followed after the first year of operation, the results were satisfactory in 84.2 per cent., and unsatisfactory in 15.8 per cent., while of the pyloroplasty cases, numbering seventy-eight, the results were satisfactory in 93.6 per cent., and unsatisfactory in 6.4 per cent. The end results in the gastro-enterostomy cases showed a percentage of 77.2 per cent. of satisfactory recoveries, while the pyloroplasty cases showed a percentage of 88.6 per cent. It is quite evident from this study that the immediate as well as the final results are clearly in favor of pyloroplasty. The only indications in favor of gastro-enterostomy are, in those instances in which there is an inability to mobilize the duodenum when adhesions are too dense, and in those cases in which there is a thickening and infiltration about the pylorus due to hypertrophic ulceration, conditions, however, which in their experience occur but rarely.

6. Abstracted in The Journal, July 3, 1915, p. 150.

7. **Treatment of Diabetes.**—The method which has been employed by Joslin in the treatment of these cases has been similar to that recommended and described by Allen. The more closely his directions have been followed the better the patients have done. No patient has required more that five days to become sugar-free. Many patients became sugar-free after the omission of three or four meals. Patients are put to bed and the plan of treatment is carefully explained to them. They are furnished with notebooks in which answers to their questions are recorded, taught the use of a diet card and how to examine the urine for sugar with Benedict's solution. So far, no patient whom Joslin has taught to test his own urine during the last year has died. He is coming to feel that coma no longer represents the culmination of the disease, but that it is an avoidable accident.

10. **Splenic Enlargement in Syphilis.**—One hundred cases of early syphilis were studied by Wile and Elliott. Of these nine cases were primary syphilis alone, the remaining ninety-one were cases in the first months of the infection, for the most part with cutaneous or mucous membrane involvement. Of the 100 cases examined, definite splenic enlargement was found in thirty-six. The spleen was noted as being hard and firm in seventeen cases, in six it was noted as tender, and in three as soft. Of the thirty-six positive cases the general health was definitely affected in twenty-seven and the remaining nine showed no impairment of the general functions. Severe involvement of the general health was found in four cases. This entailed in one case a loss of 50 pounds in weight. Expressed in terms of percentage, 78 per cent. of those cases in which the spleen was enlarged were cases in which the general health suffered considerable deterioration. On the other hand, it must be noted that the general health was affected in 22 per cent. of the cases in which enlargement of the spleen was not present. Definite involvement of bone, including under this heading ostalgia, arthralgia, periostitis, and arthritis, was found in fifteen of the thirty-six cases, or in 41 per cent.

Of the twenty-five cases in which both the neurologic examination and the spinal fluid was studied, nineteen showed definite involvement of the nervous system. Nineteen occurred coincident with a papular efflorescence; sixteen cases of the thirty-six had associated mucous membrane findings, four had alopecia. In two out of the nine primary cases the spleen was definitely palpable; in both of these there was, as yet, no general adenitis, nor was there any sign of hematogenous infection. In twenty-seven cases in which counts were made fourteen showed a leukocytosis of over 10,000, and of forty cases in which blood examinations were made and in which no splenic tumors are demonstrable, sixteen had a leukocytosis of over 10,000. With regard to the type of the splenic enlargement, by far the largest number were firm and readily palpable. The average enlargement extended about two finger breadths below the costal margin. The softer spleens, of which there were nineteen in the series, presented fully rounded margins, and were distinctly of the type that one encounters in typhoid and other acute infections. The incidence of pain and tenderness on pressure were noted in six cases, in one, at least, pain was noted as exquisite. In this case, however, although the enlargement persisted for a considerable time, the pain was promptly relieved by the antisyphilitic treatment.

12. **Appendicitis as Sequela of Tonsillitis.**—The following points are emphasized by Anderson. The importance of bearing in mind the liability of appendicitis to follow acute tonsillitis. That the appendicular involvement may be only part of generalized infection, hence the gravity of such cases is out of proportion to the local symptoms. The tendency for such cases to be atypical in their clinical course, and after smouldering, to suddenly develop fulminating symptoms. Chronic tonsillar infections should be kept in view as the possible cause of similar infections of the appendix. That whereas at least some degree of local tenderness and rigidity are almost always to be elicited on careful examination of the abdomen in the right iliac region in acute appendicitis, in rare cases these signs may be absent.

17. **Respiratory Signs in Trichinosis.**—One hundred and two cases of trichinosis are reviewed by Minot and Rackemann. The diagnosis in 70 per cent. of these cases was made by finding the embryo in excised pieces of muscle or in the blood; in 5 per cent. no parasite was found, but the muscle showed a histologic picture of a myositis such as is found when trichinae are present; in 25 per cent. by the history, symptoms, and physical signs, and the eosinophilia which varied from 13 to 63 per cent. of the total leukocyte count. All of the 102 patients recovered except one and it should be noted that although this patient had moderate dyspnea, no abnormal physical signs in the lungs were detected. In 50 per cent. of the 102 cases studied there is no mention of cough or abnormal lung signs at any time during the course of the disease, but in the remaining 50 per cent., sixteen patients (15.6 per cent.) had cough without abnormal physical signs in the lungs, while seventeen (16.6 per cent.) had cough with abnormal lung signs, making thirty-three patients (32.3 per cent.) that had cough beginning from one to twelve days (usually two to six) after the onset of the disease and lasting three to twenty-five days or thoughout the course of the illness; eighteen patients (17.6 per cent.) had abnormal signs in the lungs without cough, making thirty-five patients (34.5 per cent.) that had abnormal physical signs in the lungs. These physical signs were present within forty-eight hours after the patient entered the hospital in thirty-two cases (31.5 per cent.), and in three cases (2.9 per cent.) within six days. The duration of these signs seemed to depend on the length of time the temperature remained elevated, the signs disappearing as the temperature fell. If the signs were slight they existed as a rule, but for a few days, and only at the height of the fever. Nine cases (8.8 per cent.) showed respiratory signs or symptoms, or both, severe enough to lead to a serious consideration or actual diagnosis of a purely pulmonary condition during the first few days the patients were in the hospital.

18. **Myocardial Efficiency.**—In the estimation of myocardial efficiency, Schoonmaker says, systolic blood pressure and pulse pressure variations together with changes in pulse rate in relation to postures and light exercise have positive value. Under the test described, an increase in systolic pressure together with a stationary or increased pulse pressure is suggestive of fairly good myocardial efficiency. A decrease in systolic pressure together with a decrease in pulse pressure is suggestive of poor to bad myocardial efficiency. In these determinations Schoonmaker takes the pulse, systolic blood pressure and diastolic blood pressure with the patient reclining and fully relaxed; then he has him walk at his ordinary speed about 75 feet and repeat the test in the standing position. This exertion is not sufficient to cause such subjective symptoms as dyspnea, palpitation, or chest pain unless the heart muscle be much impaired. It should not do this. It is a postural test plus only sufficient exertion to mildly stimulate the cardiovascular system.

32. **Perforation of Ulcers of Stomach and Duodenum.**—The cases on which Walker's paper is based were gathered

from the surgical records of the Boston City Hospital for the years 1905 to 1914, inclusive. The series covers seventy-eight cases, operated on by seventeen surgeons. The technic was, in general similar, and the operative results practically the same. Males were found to have been affected more frequently than females, in the proportion of 12 to 1. A definite alcoholic history was given in 66.6 per cent. Of those who succumbed 78 per cent. used alcohol in more than moderation. The site of the perforation was found to have been in the stomach in forty-two cases, and in the duodenum in thirty-six cases. The perforations of the stomach were invariably located within 1½ inches of the pylorus. In all except two, the site was on the anterior wall, and generally nearer the lesser curvature. The perforations of the duodenum were all found on the anterior wall except one.

In this series the peritoneal cavity was generally irrigated in twenty cases, with nine deaths and eleven recoveries. All the cases irrigated showed a peritonitis more or less marked. Of those cases showing peritonitis, which were not irrigated, there were nine, with five deaths. In twenty-nine cases in this series, cultures were taken from the fluid in the peritoneal cavity. Of these, fourteen showed bacterial growth, and fifteen were negative. Peritonitis was the cause of death in fourteen of the twenty-one cases. Occasionally it resulted in a localized abscess in the pelvis, right lower quadrant, or subphrenic region. Postoperative hemorrhage and shock were the cause of death in three instances. Pneumonia occurred six times, with four deaths. The other complications recorded were pleurisy with effusion, and abscess of the lung with recovery in each case. In this series of cases, there were fifty-seven recoveries and twenty-one deaths, a mortality of 26.9 per cent. Of those who recovered the average duration of the perforation was fourteen and one-half hours, and of those who died thirty-seven and one-third hours. Seventeen were operated on during the first four hours and all recovered. Of those operated on from five to twelve hours after perforation, the mortality was 17.9 per cent.; of those operated on from thirteen to twenty-four hours, 47.6 per cent.; and of those from twenty-five to forty-eight hours, 66.2 per cent. Ten were operated on after forty-eight hours, with five deaths and five recoveries. Of those who recovered each had a walled-off abscess, and not a generalized peritonitis, thus accounting for the recoveries.

37. **Hereditary Epilepsy.**—One hundred and fifty-seven cases were studied by Thom to determine the relation between the hereditary factor in the forebears and the age of onset of the epilepsy in the offspring. One hundred and twenty-six cases had direct heredity (that derived from parents or grandparents), and thirty-one cases had collateral heredity (that shown in members of the family other than parents or grandparents). There were 293 heredity defects in the 157 cases, occasionally one member of the family having more than one defect, and in other instances two or more relatives being defective. Ninety-six (61 per cent.) of the cases gave a family history of but one defect; forty-seven (30 per cent.) had two defects and the remaining fourteen cases (9 per cent.) had three or four defects. Epilepsy was met either alone or in combination eighty-eight times (57 per cent.), alcohol fifty-nine times (38 per cent.), insanity forty-three times (27 per cent.), migraine thirty-seven times (24 per cent.), and feeblemindedness sixteen times or 10 per cent. of the total number of cases. In 95 per cent. of the cases in which alcohol, migraine or feeblemindedness was the defective factor the heredity was direct, while only 56 per cent. of epilepsy and insanity came from the forebears. In seventy of the ninety-six cases, or 73 per cent., the heredity was direct, in the remaining twenty-six cases, collateral; in twenty-five of this latter group the mental defect was either epilepsy or alcohol.

57. **Hexone Bases of Malignant Tumors.**—In five cases of malignant tumor examined by Kocher the quantity of hexone bases was approximately double that found in normal tissue. He says that these results suggest a new approach to the study of the cancer problem, especially as it relates to metabolism. Whether such high percentages of the hexone bases is a peculiarity of malignant tumors, or whether such an increase will be found in normal rapidly growing tissue is a problem now under investigation by Kocher.

68. **Dextrose and Diastase Content of Blood.**—Ten dogs were fed on a mixed diet for a period of about a week. At the end of that time they were anesthetized for two hours. The dextrose and diastase contents of the blood were determined at intervals before and during the anesthesia. The animals were then fed on a meat diet for a similar period, and the sugar and dextrose determinations made as before, during and after ether anesthesia, in such a way that the concentration of each could be directly compared. The results indicate the following: Ether anesthesia causes a hyperglycemia, which is greater in dogs fed on a pure meat diet than on a diet including carbohydrate. Ether itself, and not asphyxia or excitement, is responsible for the greater part of the blood sugar change. Ether anesthesia does not increase the diastatic power of the blood serum. The diastase concentration of the blood is on the average higher in animals which have been fed on a meat diet than on a mixed diet.

71. **Experimental Diabetes in Canine.**—The progress of experimental diabetes in the canine, though extremely rapid in comparison with the chronic course of diabetes in man, Homans says, resembles it in many respects. The administration of carbohydrate food intensifies the waste of dextrose and hastens the progress of both diseases. In both, the body becomes emaciated by burning as many of its own tissues as are available. In both, there is a tendency to a fatal outcome. The life of a human diabetic, however, is lengthened if the individual is kept free, by dietary measures, from carbohydrate waste (glucosuria). A similar observation is suggested by the experimental observations of Homans, and has been actually demonstrated by Allen and applied by him with encouraging evidence of success in man. Homans believes, therefore, that experimental and human diabetes are, therefore, strikingly alike. The experimental disease is due to a functional deficiency on the part of the islands of Langerhans. Diabetes of man, in the author's opinion, has in all probability a similar immediate etiology.

72. **Study of Scharlach R Reaction.**—The experimental data obtained by Bullock and Rohdenburg lead them to draw the following conclusions: The Scharlach R reaction is a reparative process, acting under conditions of prolonged disturbance of mechanical equilibrium between epithelium and connective tissue, and dependent for its inception and continuation on irritation and cell death. The contact with epithelial cells of a chemical irritant of slow absorbability and relative mild toxicity is indispensable for the production of the reaction. The chemical owes its power of inducing epithelial proliferation, not to its solubility in lipoids, but to its ability to cause continuously a certain amount of tissue death. Cessation of epithelial proliferation occurs before the absorption of the foreign substance and indicates the return of equilibrium after the performance of the new task imposed on the tissues. The character and extent of the reaction are independent of the amount of blood circulating in the tissues. The degree of reaction depends on the surface area of epithelium exposed to the irritant. Scharlach R exerts no specific stimulating action on epithelial cells. The attraxine hypothesis of Fischer is untenable. Metaplasia is a frequent occurrence in the tissue of the ear, breast, prostate, and lung, after the injection of a chronic irritant of the type used in their experiments.

73. **Primary Melanosarcoma of Suprarenals.**—A case of primary melanosarcoma, arising in the suprarenal glands is reported by Maclachlan. The tumor was bilateral and almost symmetrical. A complete necropsy was performed and a most exhaustive search failed to demonstrate any primary neoplasm in the skin, choroid, or meninges. Scattered in the deep subcutaneous tissues of the trunk and upper extremity
ere many movable nodules. No mole could be found on

lung. The heart showed the presence of multiple small pigmented tumors in the musculature of the right auricle and ventricle and in the left auricle.

Examination of the abdomen showed scattered nodules beneath the peritoneum of the abdominal wall, tissues of the mesentery, liver, bowel and other viscera. Three large masses of tumor were also found, one on each side directly above the kidney in the region of the suprarenals. Each of these masses was the size of an orange. The third mass was lying posteriorly in the midline near the cardia of the stomach and attached to the left lobe of the liver. This mass was as large as a grape fruit, and its anterior surface was adherent to the stomach along the lesser curvature. On its posterior surface the mass showed a tear in its capsule and the tumor tissue was also torn. From these parts the peritoneal bleeding had its origin. Elsewhere, the tumor, which was intensely black, was covered by a thin capsule. The great omentum contained a number of nodules the size of cherries. Many of the glands in the mesentery were invaded by black growths. Tumor masses were seen through the capsule of the liver. The gallbladder showed six small, pedunculated black tumor masses at the fundus. The bile ducts were clear. Several small encapsulated black masses about 1 cm. in diameter, were seen in the pancreas, and also in the loose connective tissue and lymph glands about the organ. A single nodule was present in the spleen.

Each kidney was of about the usual size and was surrounded by a thick layer of fat, in which were studded many small black tumors. There were no tumor masses in the kidney substance proper and both organs were normal in appearance. Over the upper pole of the left kidney and in the region of the suprarenal was a large and intensely black tumor mass, 10 by 8 by 4 cm. On section the tumor was more or less lobulated and its tissues were soft and friable. It was surrounded by a thin capsule and sharply separated from the kidney substance. No remains of suprarenal substance could be found. From the renal vein, a vessel passed over the face of the tumor and entered it at the apex. Over the right kidney, in the region of the right suprarenal, was another tumor 10 by 9 by 4 cm. This tumor mass was similar in every way to the other on the left side. The right suprarenal gland could not be recognized in the tumor mass. A black tumor mass the size of a walnut was seen projecting into the cavity from the wall of the bladder at the fundus. The genital organs, rectum, and anus were without change. Microscopically the tumor differed in no way from the usual melanosarcoma which arises in the skin or in the choroid.

74. **Filterability of Trypanosomes.**—The authors found that trypanosomes from cultures and from animal tissues are not filterable through bacteria-proof filters.

76. **Action of Benzol.**—Following the subcutaneous administration of equal parts of olive oil and benzol in rabbits, the authors found that there occurs a rapid decrease in the number of leukocytes in the peripheral circulation. Following this primary fall in the leukocyte curve there occurs a primary rise, which is, in each instance, followed by a secondary fall before a permanent rise to a normal level. The primary and secondary falls in the leukocyte curves are accompanied by a marked decrease in the percentage of polynuclear leukocytes, indicating that the polynuclear leukocytes are especially affected after the injections. Coincidentally with the primary fall in the leukocyte curve, there occurred, in two thirds of the cases, a moderate but definite fall in the erythrocyte curve. The erythrocyte curve appears to progress independently of the leukocyte curve after the primary fall, and in the majority of instances remains unaffected during the secondary fall in the leukocyte curve. This fall in the erythrocyte curve was usually followed by a rise. In rabbits in which the injections are begun two days and six months respectively after splenectomy, the leukocyte and erythrocyte curves are essentially the same as in the nonsplenectomized rabbits which receive like injections, and the duration of the periods of regeneration is essentially the same. The differential counts on the nonsplenectomized animals and those animals splenectomized two days and six

months previously, show no essential differences, and the blood-cell picture is otherwise the same.

The authors are of the opinion that these observations on the leukocyte and erythrocyte curves indicate that in the rabbit the spleen serves no essential function in the destruction of leukocytes and erythrocytes, following subcutaneous injections of the olive oil-benzol mixture, or in their subsequent regeneration. Any destructive or regenerative function that it has is quickly assumed by some other part of the body when the spleen is removed. "Myeloid metaplasia" of the spleen is of no great importance as a compensatory phenomenon, and regeneration, as represented by the blood count, takes place at least as quickly in the absence of the spleen.

78 *Feebly Inhibited. Violent Temper and Its Inheritance. C. B. Davenport, Washington, D. C.

78. Feebly Inhibited.—A study was made by Davenport of 165 family histories of wayward girls in state institutions. The study of the data obtained lead the author to the following conclusions: The tendency to outbursts of temper—"tantrums" in adults—whether more or less periodic or irregular, and whether or not associated with epilepsy, hysteria, or mania, is inherited as a positive (dominant) trait, typically does not skip a generation and tends, ordinarily, to reappear, on the average, in half of the children of an affected parent. It would seem to follow from the data presented that epilepsy, hysteria, and mania are not the causes of the violent tempers, frequently accompanying them; the violent outbursts are in no clear sense the "equivalent" of these various psychoses. Rather, the violent outbursts of temper are due in all these associations to a factor that causes periodic disturbance (possibly, paralysis of the inhibitory mechanism?). This factor has the greatest effect when acting on a nervous system that is especially liable to show the other psychoses. In other words, "tantrums" are apt to be associated with these various neurotic conditions, while they have no necessary connection with them.

97. Improved Method for Repair of Lacerated Perineum.—Bernstein believes it to be a mistake in technic, to raise these flaps of mucous membrane and fascia from the center of the wound; as by so doing, the tear is deepened, the vagina is shortened, and the trauma is increased. The circulation already established is interfered with, the amount of blood and serum naturally thrown into the wound is multiplied, edema and sloughing are encouraged, infection is invited, and healing is retarded. He catches up the tissues at the entrance of the vagina, just below the lowest caruncle on either side, and separates the labia, making an incision along the crescentic border created between these points. Next, he says, separate slightly the edge of the mucous membrane from its underlying fascia. Then make an incision into the fascia, following the same line as the first one, and raise the fascia slightly from its bed. With artery clamp or suture, draw down the central point of the lower cut edge of the wound, which makes a central ridge, corresponding to the deepest part of the original tear. With blunt scissors or finger, make an opening on either side into the exposed connective tissue, leaving the center intact, and the strands of the levator muscle can easily be brought into view. Catch up the strands of the levator muscle on either side, bringing them out of the wound and together in front of the central ridge, with three or four chromic catgut sutures. Close triangles like a book, by bringing the original guiding sutures together. Suture first the vaginal side of the wound, comprising mucous membrane and fascia, from within outward, with a continuous suture. Having tightened the vaginal stitches and buried sutures, there now remains merely a straight line of fascia and skin, extending downward from the lowermost point of the vagina to the bottom of the tear, to be sutured in separate layers, with such material as the operator may select.

3. **Heart Disease and Ulcerative Sore Throat.**—In the heart of a male infant, aged 11 months, who died from bronchopneumonia, the following anomalies were present: (1) Transposition of the great arterial stems, the aorta arising from the infundibulum of the right ventricle and the pulmonary artery from the left ventricle. The walls of the right ventricle were considerably hypertrophied, being almost as thick as those of the left. Both ventricles entered into the formation of the apex. (2) Marked deficiency of the interauricular septum, which was represented by a narrow band 1.5 cm. long by 0.5 cm. broad. The foramen primum lay anterior to it, and posteriorly there was a widely patent foramen ovale. (3) An interventricular foramen, 1.2 cm. in diameter in the "undefended space." (4) Stenosis and hypoplasia of the pulmonary artery, which had only two cusps. No gross changes were found in the other organs.

22 *Acute Ulcerative Tonsillitis Associated with Virulent Pyorrhea Alveolaris. A. Ryland.

20. **Shoulder-Arm-Hand Syndrome of Paranasal Sinus Disease.**—Macnab reports three cases presenting the shoulder-arm-hand syndrome described by Bliss. They occurred in males between the ages of 20 and 40, and all complained of the shoulder-arm-hand pain. One was sent on account of tonsillar pain of two years' duration, the upper limb pain having lasted over three years. Two of the patients had also occipital pain. The nasal cavity showed in one case septal deviation to the affected side with a crowded middle turbinate, and a faint trace of mucopus in the olfactory cleft. In the other two cases there was enlargement with polypoid degeneration of the mucous lining of the middle turbinate, but in these cases little pus was detected anteriorly even after shrinkage with epinephrin. However, all had sufficient evidence for an exploration of the posterior ethmoids and sphenoids which showed that the main pathologic condition was enlarged cystic cells easily broken down and lined with unhealthy and diseased mucous membrane. Exenteration of the posterior cells as completely as possible was carried out, while the whole anterior wall of the sphenoid was removed. Within a comparatively short time all acknowledged that their symptoms were decidedly better. It is difficult to account for this referred pain, at least anatomically, but that it does occur is evident from the reported cases.

22. **Ulcerative Tonsillitis Associated with Pyorrhea Alveolaris.**—Ryland's patient complained of sore throat, of sudden onset and of five days' duration. There was excavation of tissue in three or four separate and distinct areas on the buccal surface of each tonsil. The ulcerated edges were clear cut, but irregular, and surrounded a greyish sloughing base. The neighboring inflammatory areola was only slightly marked. There was no edema, little pain, and the fauces, palate and uvula were free from inflammatory change. The tonsillar lymphatic glands on each side were slightly enlarged. The nose revealed an extreme anterior deviation of the cartilaginous septum to the right side, probably of traumatic origin. The patient was a mouth breather. Syphilis was denied. The Wassermann test was not carried out. Solution of silver nitrate, 20 per cent., was applied daily to the ulcerated areas, which under this treatment began to improve, and healed almost completely by the seventh day. On the sixth or seventh day of treatment, there suddenly appeared an acute, virulent and rapidly progressing septic invasion of the gums of both upper and lower jaws. The gums rapidly became soft, spongy, and tender. Pus was seen to be freely exuding from between them and the teeth. The temperature rose.

There was headache, malaise, the patient was toxemic, and the decision was almost made to remove freely the infected teeth. Pure phenol and other remedies were used locally without effect. Eventually under the influence of hydrogen peroxid the infection left the mouth almost as suddenly as it had appeared. The pyorrhea lasted for eight days. No mercury or other antisyphilitic remedies had been given. A bacteriologic examination of the alveolar exudate during the height of the infection revealed a pure growth of a long-chained Gram-positive streptococcus, of unusually large size as regards the cell bodies. With methylene blue, there was definite bipolar staining. No cultural examination was made from the original lesion, but it would appear highly probable that the same organism was responsible for both the tonsillar and alveolar infections. A point of interest is the extreme rapidity with which the organism surrendered to hydrogen peroxid.

30 Economy in Food During War. A. K. Chalmers.

26. **Autogenous Vaccine in Undulant Fever.**—In the case cited by Owen and Newham an autogenous vaccine was prepared and an initial dose of approximately 200,000,000 organisms was administered on December 4. No ill effects followed the administration of this dose, and on the sixth it was seen that the temperature had fallen to normal, and with the exception of a slight rise to 99 F. on the evening of that day and two subsequent rises to 99, it remained practically at the normal point until December 12. It then commenced to mount again in the typical manner of undulant fever until the fifteenth, when a second dose of the vaccine was given (200,000,000), and up to Jan. 4, 1915, the temperature, beyond a few slight rises to about 99.2 remained fairly normal, and the patient showed marked improvement in his general condition. A third dose of vaccine was administered on December 24, as the temperature was a little irregular.

The patient expressed himself as feeling well as a result of the injections. Sweating was absent; he increased in weight and had a general feeling that he was improving markedly. On January 4 a fourth dose of vaccine was given, but on the fifth the temperature suddenly rose, accompanied by rigor, to 105, and a typical attack of lobar pneumonia developed. (At this time there were three acute cases of pneumonia near him in the ward.) The temperature fell by lysis and remained somewhat irregular till January 26 when it finally came down to normal and remained so until the patient's discharge on April 7. In all only four doses of the vaccine were administered. In view of the known inefficacy of ordinary medicinal preparations to in any way alleviate the symptoms or control the progress of this disease it is satisfactory to record that in this case improvement was obtained by the use of an autogenous vaccine. Previous reports of treatment with stock vaccines have not been encouraging.

27. **Quinin in Experimental Gaseous Gangrene.**—The results of Taylor's observations may be briefly summarized as follows: *A.* Quinin has shown a marked bactericidal activity against the gas bacillus. 1. It has inhibited its growth in vitro, in which it was ten times as effective as phenol. 2. It has reduced the mortality from gaseous gangrene in animals from 100 to 41 per cent. *B.* Quinin has shown strong laboratory evidence of value as a general antiseptic. 1. Its general bactericidal power was higher than that of phenol. It was especially effective in a menstruum of pus. 2. It did not damage healthy tissue in local injections of effective concentrations. It is known to produce local anesthesia, frequently a desirable result. 3. It produced no symptoms of intoxication in the animals treated. It was used in hypertonic solution. 4. It showed a strong antitryptic action in vitro. On the evidence of these experiments a 1 per cent. solution of quinin hydrochlorid is now being tried by Taylor for the treatment of gaseous gangrene and other infections. A report on the result of its use will be published later.

28. **Agglutination Reactions of Blood of Soldiers.**—The preliminary inquiry made by Dakeyne of which this paper gives a summary, deals chiefly with the power which the blood of persons inoculated with dead typhoid bacilli has to agglutinate the *Bacillus typhosus* and some allied bacilli and is based on the examination of 280 soldiers who had received one or more injections of antityphoid "vaccines" within the previous twelve months. The tests were made according to the Delépine method, with dilutions of approximately 1:20 in current work, controlled, when thought desirable, by further tests with exactly measured 1:30 dilutions. The time limit was in all cases two hours. The serums were tested against a typical *Bacillus typhosus,* also against *Bacillus paratyphosus* B, and a *Bacillus enteritidis* (7,160) obtained recently from a typical case of food poisoning. The men examined were under treatment in the Manchester military hospitals for either wounds or illness.

Over 80 per cent. of cases gave a definite reaction, while 16.4 per cent. gave no reaction. Further, a man inoculated twice has a much greater chance of developing and retaining a reaction than one inoculated only once. There is a gradual diminution in the reaction as the result of the lapse of time. This is especially marked at the end of the eighth month. Only one case out of nineteen examined within a month of inoculation was found negative. This man had been inoculated once only and his serum, though giving no reaction with the *B. typhosus* used, gave a marked reaction with a strain of the *B. paratyphosus* B. There was no history of paratyphoid infection. If this case be excluded, all those examined within a month of inoculation gave a reaction. It appears that after the end of the first month the reaction is liable to disappear rapidly. Seven men were examined who had not been inoculated within a year. Three, who had been inoculated from twelve to eighteen months previously, were negative; three others, inoculated once each, fourteen, twenty-four and forty-five months previously, respectively, gave strong reactions. One man inoculated five years before, gave a slight reaction. This suggests to Dakeyne that individual peculiarity may have an effect deserving consideration.

32 *Effectual Action of Fuchsin in Treatment of Impetigo and Suppurative Skin Disease in General. C. Ferreira.
33 Lymphogranulomatosis in Boy of Five. (Maladie de Sternberg.) Blanc.
34 Tuberculosis of the Liver in Infant Under Four Months. H. Barbier.
35 Congenital Deformity in Lower Segment of Spinal Cord. (La myelodysplasie de Fuchs.) J. Comby.

31. **Spastic Rigidity in Children.**—Comby is convinced that Little's disease can be traced to syphilis in some cases, to birth trauma in others, or to acute encephalitis, primary or secondary to infectious disease. In other cases its origin is unknown. He compares here the clinical pictures in thirteen cases of the typical form of Little's disease, seven of spastic rigidity entailed by acute encephalitis, and eighteen of obstetric origin.

32. **Fuchsin in Treatment of Pyodermitis.**—Ferreira has been much impressed with the benefit from local application of fuchsin in a number of cases of impetigo, intertrigo and other rebellious skin affections in infants. The details of twelve cases are given.

He uses the ordinary bacteriologic fuchsin stain, Ziehl's carbol-fuchsin solution, which he prepares by dissolving 1 part fuchsin in 10 parts alcohol, with 5 parts phenol and 100 parts distilled water. He has used this in hundreds of cases and never noted any signs of absorption of phenol, the urine never showing any disturbance in color or composition. With this technic there is no need for a dressing. The fuchsin mixture is applied on cotton to the crusts, pressing it into each after all loose and friable parts of the crusts have been removed with sponges dipped in a 1:1,200 solution of zinc sulphate or its equivalent. The crusts absorb the fuchsin mixture and harden, forming an impermeable red varnish. It is applied anew each day and the crusts gradually grow smaller and smaller. The only drawback is the possible staining of the linen.

Presse Médicale, Paris

August 30, XXIII, No. 40, pp. 321-332

36 *Lesions of Trunk Nerves in War. V. (Les lésions des gros troncs nerveux des membres par projectiles de guerre. Les différents syndromes cliniques et les indications opératoires.) Dejerine and J. Mouzon.

36. **Wounds of Trunk Nerves.**—Professor Dejerine, Mme. Dejerine and J. Mouzon here present the fifth instalment of their extensive study of gunshot and shell wounds of trunk nerves in arms and legs, the syndromes resulting and the indications for operative treatment at the time or later. They are in charge of a hospital specializing in treatment of such cases. The wounded do not reach this hospital until about six weeks after the injury, and the writers say that until at least this interval has elapsed, the neurologic findings are not conclusive for or against operative measures. They discuss in this instalment what they call the dissociated syndromes, comparing the clinical with the operative findings in cases from their service and deducing the indications for operation. The general diagnosis is also discussed, the sources of error, the objective symptoms, modification of the reflexes and the changes in the tissues and in the response to electric stimuli, concluding with a discussion of the technic, showing the procedures to be commended and those to be shunned, with concrete instances. The article is illustrated. In certain cases the symptoms of compression soon after the injury subsided spontaneously in a few weeks, to a complete cure by the end of a few months. The trauma must have caused the compression and, when this ceased to act, repair started at once. This is very different from permanent compression or secondary compression, for both of which operative relief is indispensable. The Society Proceedings also contain a detailed summary, by the same writers, of their experiences with forty-two cases of wounds of the spinal cord. With an injury of this kind, they say, the best time for operative treatment is between the fifteenth and the thirtieth days if operative intervention is required. Before this, the shock and the lesions in the

vicinity blur the differential picture, and later than this bladder infection becomes troublesome and cicatricial changes impede restoration of function.

39 *Appendicitis and Typhoid. G. Wolfsohn.
40 Operations on Soldiers from Standpoint of Regaining Military Efficiency. (Zur Frage des operativen Eingriffes bei Heeresangehörigen.) P. Weimann.

39. **Typhoid Localizing in the Appendix.**—Wolfsohn has had a number of men sent to the base hospital in his charge with the diagnosis of appendicitis. The men had not been taken sick suddenly, but for some days or weeks had felt depressed and ailing, sometimes with headache and pains in the limbs, and always with diarrhea and abdominal pains. The men had been taking castor oil or opium for the diarrhea but it returned after the medication, and blood had been noticed in the stools in some cases. The aspect is more that of health than usual with appendicitis, but the region of the cecum is tender although the abdominal wall over it is not rigid but quite soft. Bacteriologic examination of stool, urine and blood for typhoid bacilli is constantly negative. He removed the appendix in ten of twelve such cases and all the symptoms subsided at once, and in ten or twelve days the men were entirely well. The lesions in the appendix were never very pronounced, but in a number of the cases typhoid or paratyphoid bacilli were cultivated from the inner wall of the appendix although none could be found in the blood, urine or stools. In two cases the diagnosis was acute appendicitis and the appendix presented the usual lesions of this and contained typhoid and colon bacilli, streptococci and staphylococci. All the men had been systematically inoculated against typhoid, and Wolfsohn is convinced that this had rendered the tissues so resistant to typhoid infection that the typhoid bacilli could find no lodgment except in the appendix. It is possible that typhoid bacilli may lurk in the appendix, as we know they do sometimes in the gallbladder, without causing appreciable symptoms.

Deutsche medizinische Wochenschrift, Berlin

August 26, XLI, No. 35, pp. 1025-1056

48 Tuberculosis at Shanghai. H. Dold.
49 Splint for Fracture of Humerus. (Innenschiene bei Oberarmbruch.) L. Engelhardt.
50 Treatment of Abdominal Wounds. (Zur Behandlung der Bauchschussverletzungen im Felde.) W. von Brunn.

41. **Deposits of Coal Dust in the Intestine.**—Lubarsch found macroscopic deposits of coal dust in the Peyer's patches of a man of 60. This pseudomelanosis might very readily have been mistaken for relics of blood accumulations, and it is in this way that such cases have been interpreted in the past. But Lubarsch presents evidence as to the true coal-dust nature of the deposits, especially their localization exclusively in the lower Peyer's patches of the ileum to 1.10 m. above the valve; their color, shape and chemical behavior, and the frequency of this finding when systematically sought for, regardless of inflammation, hemorrhages or other morbid processes. Since he has been examining for it systematically he has found it in 31.2 per cent. of 280 cadavers: in 6 from 2½ to 6 years of age; 6 from 10 to 20; 8 from 20 to 30; 14 from 30 to 40, and the others above this age. He also found similar deposits in the bowels of a guinea-pig. In a number of th[illegible]vers there was but little tendency to anthracosis in [illegible] For these and other reasons enumerated he [illegible] there can be no doubt that the coal dust gets into the villi by being swallowed. The findings sustain the assumption that infection with tuberculosis occurs both by way of inhalation and the food.

42. **Improved Technic for Cultivating Cholera Germs.**—Aronson's method is based on the specific splitting of cane sugar added to an Endo plate, and the ability of cholera germs to proliferate in mediums too alkaline for colon bacilli. The technic is described in detail and the method styled the easiest and the most certain means at our command for detecting cholera germs, especially in carriers and in comparatively symptomless cholera.

43. **Diagnosis of Heart Disease.**—In concluding this long review of the diagnosis of heart disease by the general practitioner, Rosin says that the old and tried methods of examining for heart disease have lost none of their importance in comparison with the newer methods. But a thorough examination now should include certain of the newer methods, especially measurement of the blood pressure, palpatory percussion, Roentgen examination and the Wassermann test. Electrocardiography is also useful, affording information not obtainable in any other way. But the findings have not been interpreted to date with sufficient accuracy to justify recommending to the general practitioner the purchase of the extremely expensive apparatus required for it.

44. **Post-Typhoid Paralysis.**—Zadek reports the case of a boy of 9 convalescing from typhoid who developed right hemiplegia with loss of reflexes. It was evidently of cerebral origin, the work of the typhoid, and it rapidly improved under electric treatment, massage and baths and by the end of the month had retrogressed almost entirely.

46. **Ovariotomy During Pregnancy.**—Unterberger reports the details of eight cases in which ovariotomy was done on pregnant women. In one of the women it was bilateral, and abortion followed in this case, but the pregnancy was not interfered with in the other cases. He advises to postpone the ovariotomy until the third or fourth month if possible, as there is less danger of interrupting the pregnancy after this.

47. **Treatment of Erysipelas.**—Szecsy has been much pleased with the efficient action of a mixture of 10 parts each of guaiacol and tincture of iodin in 80 parts glycerin, applied as a lininent to the erysipelatous region. It has merely a symptomatic action, but in this it far surpasses all other measures of which he knows.

Medizinische Klinik, Berlin

August 15, XI, No. 33, pp. 905-932

51 *Urology and War. (Urologische Erkrankungen im Kriege.) R. Oppenheimer.
52 Hernias from Industrial and Other Accidents. E. Schepelmann.
53 *Autoserotherapy of Gangrenous Venereal Ulcer, etc. (Behandlung des Ulcus molle gangraenosum und anderer Ansteckungskrankheiten mit Eigenstoff, Eigenserum oder Eigenblut.) W. Treupel.
54 Mixed Infection with Typhoid. H. Koenigsfeld.

51. **Urology on the Firing Line.**—Oppenheimer remarks that there has been no great war since the modern methods of urologic investigations have been introduced, and he has utilized the present war to collect data in this line. The summaries of sixteen cases are given to illustrate the various types encountered, both of wounds and of urologic affections such as are observed at any time but for which the stress of the campaign induces a predisposition and creates exciting causes. He says in conclusion that in calculating the indemnity, he estimates that the loss of one kidney reduces the earning capacity on an average about 45 per cent.; a traumatic detrusor paralysis, from 50 to 80 per cent.—on account of the danger of secondary pyelonephritis—and permanent incontinence, from 70 to 80 per cent.

53. **Autoserotherapy for Gangrenous Venereal Ulcer.**—Treupel relates that in two progressive cases of this kind, long uninfluenced by vigorous local measures, injection of the patient's own serum seemed to arrest the gangrenous

process, and start the patient on the road to recovery. In the first case the gangrenous ulcer scabbed over and the scab was thrown off the fifth day. Three injections of the patient's own active serum were given, in the course of four days, the amounts ranging from 10 to 24 c.c. In the second case four times these doses of serum or 100 c.c. of the blood were given and prompt benefit was apparent, the gangrene promptly healing. Febrile skin affections were likewise favorably influenced. In one case of petroleum eczema, with temperature of 40.4 C. (nearly 105 F.), the fever rapidly dropped and the skin affection retrogressed after a venesection of 50 c.c. of blood and intravenous injection of 200 c.c. of the patient's own blood. The cure was completed by two further injections in four days. The work issues from the university clinic for skin diseases at Jena, in charge of Spiethoff. He has found this "own blood" or "own serum" beneficial also in treatment of catarrhal febrile sore throat and prostatitis, typhoid and tetanus.

55. **Diabetes Insipidus After Trauma of the Skull.**—Kleeblatt relates that a robust young mechanic was rendered unconscious for ten minutes when a wheel from a pulley fell on his head from a height of over 9 feet. The base of the skull was fractured, and the third day afterward symptoms of central severe diabetes insipidus appeared and have persisted since. Roentgenoscopy reveals nothing abnormal; the hypophysis region in particular seems intact. The specific gravity of the urine showed no rise even under long abstention from water and ingestion of salt. Hypophysis preparations induced a transient increase in the total concentration power, but the general health did not benefit by this. The blood findings are within normal range. During periods of abstention from drinking water, the output of urine materially surpassed the intake. The blood became much more concentrated also.

70 Microphotography. (Praktische Winke für Mikrophotographie.) Stange.

59. **Cardiovascular Disturbances from Shock Toxins.**—Mautner and Pick report research on dogs, cats and rabbits, studying the drop in blood pressure after intravenous administration of some albumin cleavage product. The shock action seems to be in the nature of a spasm of the nonstriated muscle in general and particularly of the musculature of the vessels of the intestines, liver and lungs. Drugs which dilate the vessels, such as amyl nitrite, arrest the spasmodic contraction and thus check the shock action. This explains the favorable influence of caffein in conditions resembling shock, as after antityphoid inoculation in exceptional cases. Its vasodilating action counteracts the spasm from the shock toxins.

60. **Regeneration of Agar.**—Mohorcic says that in the course of the eleven months of war the supply of agar-agar has been mostly used up, and hence he has been evolving a technic to render it possible to use agar-agar over and over again in bacteriologic research.

61. **Acute Yellow Atrophy of the Liver in Syphilis.**—Bendig's patient was a robust young woman nine months pregnant. She was given mixed mercury and salvarsan treatment on account of a primary syphilitic lesion. The first two injections of salvarsan caused no disturbance but she vomited after the third, and two days later symptoms of acute yellow atrophy developed, fatal within two days. He reported in 1908 an almost identical fatal case in a young woman but this was long before salvarsan was invented so that the salvarsan need not be incriminated in the present case.

71. **Present Status of Disease of the Bile Apparatus and Pancreas.**—Hochhaus regards cirrhosis of the liver as the result of a number of interacting causes which explains why it is so refractory to treatment. Referring to the bile secretion, he calls attention to recent study of the secretion of bile in a man with a fistula into the liver (Ignatowsky). Animal albumin stimulated the production of bile much more than vegetable albumin, and fat even still more. Mineral waters, on the other hand, checked the secretion of bile. These findings confirm empiric experiences. Reach reported last year that morphin, epinephrin, pilocarpin and atropin increased the tonus of the sphincter at the papilla of Vater and thus retarded the outflow of bile, while papaverin relaxed this sphincter. Hence the latter might relieve in jaundice in which spasm of this sphincter is a factor. In the diagnosis of pancreas disease, an excess of creatin or fat in the stools is easier to determine and more decisive than the ferment content. Hustin's recent research has confirmed the statements as to the stimulating action of pilocarpin on the pancreas. He found (experimentally) that this action was not direct but occurs only when part of the intestine is functionally capable. When this is the case, pilocarpin intravenously stimulates pancreatic secretion. Sodium bicarbonate seems to have the opposite effect, depressing pancreas secretion. Wilbrand concludes from his study of this subject that sodium bicarbonate can be relied on to check the external secretion of the pancreas while the internal is probably stimulated by it.

72. **Gynecologic Hemorrhage.**—Wagner remarks that the introduction of organotherapy and of radiotherapy have contributed to do away with hysterectomy for genital hemorrhage. We have learned that what used to be called hypertrophic and hyperplastic endometritis is in reality not endometritis at all, but a physiologic change in the uterus lining which occurs periodically under the influence of the functioning of the ovaries. We have learned further that true endometritis does not induce hemorrhage.

The physiologic menstrual hemorrhage is influenced by the behavior of the blood vessels, their innervation and the composition of their walls; by the composition and condition of the uterine musculature, and also by the condition of the blood with respect to its coagulating power. Any one of these three factors may become deranged, so that even with normal ovarian functioning there may be pathologic hemorrhage. The hemorrhage may thus be of mechanical origin or of ovarian origin, and classification of the cases points the way to effectual treatment. The mechanical group includes the cases of hemorrhage from polyps, erosions and myomas located beneath the mucosa which stretch and tear the vessels above them. Another group includes the cases of abnormal hyperemia of the uterus, from psychic, thermic or sexual causes, or from high blood pressure, tight lacing or constipation. Other groups of mechanical hemorrhage include the cases of defective contraction of the uterus from muscular insufficiency; arteriosclerosis or syphilitic changes in the vessel walls; deficient coagulating power; constitutional disease; and, finally, the peculiarly persisting tendency of hemorrhage with extra-uterine pregnancy.

In contrast to all these so-called mechanical groups, are the hemorrhages for which ovarian functioning can be incriminated. The typical forms of this occur in puberty and at the menopause. When the ovaries are dying off, they are like a lamp that is going out but flickers up now and then. The Abderhalden test confirms the dysfunctioning of the ovaries in these cases, as also in hemorrhage with chlorosis and obesity, but above all with myomas and affections of the adnexa. In certain cases the hemorrhage may be traced to abnormal functioning of some other of the glands with an internal secretion, closely connected with the ovaries. Sehrt has differentiated a group in which the hemorrhage is the result of thyroid insufficiency; the blood in these cases coagulates abnormally fast. The list of these groups closes with those in which there is actual hyperplasia of the uterine mucosa for which the ovaries are directly responsible, and the cases of necrotic processes from incomplete menstruation.

Classifying the case as mechanical or of ovarian origin, and in one of the above subgroups, points the way to causal and effectual treatment. The mechanical require local measures, and the first step is to exclude cancer. Unless this can be done with certainty, no attempts at conservative measures are justified. Here the curet is almost indispensable. The old idea that curetting would put an end to the tendency to hemorrhage, as a new mucosa grows out, has been proved erroneous—the new mucosa is under the influence of the ovaries as much as the old. Permanent benefit was realized in less than 10 per cent. of 600 curetted cases on record. Cauterization is equally futile, as a rule, but tamponing the uterus is still, as ever, a reliable symptomatic measure to arrest bleeding. Removal of the cause may require cold sitz baths, digitalis if there is cardiovascular derangement, or calcium lactate by the mouth to tranquillize the overexcitable nervous system which is keeping up the active hyperemia in the genital organs. When the uterus is unduly flabby, ergot may help. Something of the kind given a few days before the period may ward off the tendency to excessive hemorrhage; electricity may also prove useful.

Organotherapy or radiotherapy or both are now at our disposal for the cases of ovarian origin, and give most gratifying results. They have aided in classifying cases, as when a case proves refractory to radiotherapy, for instance, this proves that some other factor is at work, unsuspected syphilitic changes or a submucosa site of a myoma, permitting, then, proper treatment. The effect of radiotherapy is prompter and more certain the nearer to the extinguishing of ovarian function. The great drawback is the danger of overlooking cancer. A number of such mishaps have been reported. Wagner applies radiotherapy by the close, filtered, crossfire technic. Loose has reported excellent results in juvenile menorrhagia from small doses (2 or 3 X per ovary) with medium hard tubes, applied during the hemorrhage. After three or four exposures the hemorrhages are kept within normal range. The pathologic elements in the ovary seem to be corrected by this mild radiation while the normal elements do not feel its influence.

73. **Cholera Infantum.**—Langstein insists that with albumin milk correctly given complete recovery may almost be guaranteed. The infant with diarrhea and vomiting is given nothing but tea for from twelve to twenty-four hours, no longer, and then the albumin milk is commenced, not over 5 gm. ten times a day, with 3 per cent. of a maltose-dextrin mixture. The amount of albumin milk is increased by 50 gm. each day until the daily ration totals 300 gm. After the weight has become stationary, carbohydrates can be added up to 5 per cent. of the maltose-dextrin mixture. With a child over 3 months old, 1 or 2 per cent. flour or oatmeal can be added. He warns against giving too small a daily ration; especially serious is an undue restriction of carbohydrates. This is particularly dangerous for infants who have reached the stage of "decomposition." The nature of the albumin milk enhances the tolerance for carbohydrates. The lack of adequate carbohydrate in the food soon becomes manifest in the decline in the weight; it drops abruptly and the child collapses. The lack of carbohydrates is the more dangerous the more atrophic the child, the less reserves of carbohydrates it has to draw on. Even if the diarrhea keeps up, the ration must be increased as above described or there is grave danger of inanition.

One must be firmly convinced of the wisdom of keeping on with the albumin milk in this way, realizing that even frequent passages on albumin milk do not aggravate the condition, and that the bowel functioning will return to normal sooner or later. When the diarrhea and loss in weight have ceased, then we are less liable to disagreeable surprises and mishaps than with any other form of artificial feeding. Even if the diarrhea returns, hold steadfast to the albumin milk and the 3 per cent. carbohydrate. Any repetition of the starvation diet or withdrawal of carbohydrates may bring severe disturbances and collapse to the sick infant. A return to the starvation diet within a week may prove promptly fatal. Langstein discusses further the mishaps liable from infection or from return of the alimentary disturbance.

Albumin milk is not so uniformly effectual in dysenteriform diarrhea as in cholera infantum. Whey seems to act better, diluted half and half with oatmeal gruel. After the starvation period he gives 50 gm. of the whey and increases by 50 gm. daily with equal amounts of oatmeal gruel. As improvement sets in, 3 per cent. of a dextrin-maltose preparation can be added. He advises to make the whey artificially from the milk. Kaolin and charcoal have been given to infants as well as to adults, but no decisive judgment as to benefit from them can be drawn as yet. Their depressing action on the digestive ferments must be taken into account. The whey permits the diseased large intestine to recuperate while it supplies the salts needed by the organism. The prognosis on whey is not unfavorable, provided there is no complicating digestive nutritional disturbance. When the child has both cholera infantum and enteritis, he advises combating the former first and foremost by keeping the child on albumin milk.

74. **Roentgen Treatment of Acne.**—Dösseker says that experience is demonstrating that repeated small doses of the rays, not strong enough to induce appreciable reaction in the skin, or a single large dose with a reaction, seem to be able to modify the epidermis, that is, the sebaceous glands to such an extent that the tendency to acne dies out. His communication is based on large numbers of cases but he does not cite statistics nor bibliographic references, his aim being merely to recall attention to Roentgen treatment of acne, with his personal endorsement of it. Fortunately he adds, its efficacy is greater in acne spread over a larger surface, with numerous pustules, than in the less disfiguring, torpid type.

77. **Trademarks and Protected Names.**—Heubner reiterates that "protected" names of drugs sooner or later become the generally accepted term for the drug in question, the general term in common commercial and medical use. Legal authorities differ as to when this transformation takes place, but the fact that it does occur sooner or later is now generally accepted. Another instance of it, he relates, is seen in the labels of the drugs now supplied to the German army hospitals. Instead of the official name, hexamethylenamin, for example, the drug is labeled "Substitute for urotropin," *Ersatz für Urotropin, Ersatz für Aspirin*, etc. Tablets are supplied stamped in the same way, "Ersatz für Antipyrin, 0.5." The wrapper bears the full title, "Hexamethylentetramin, 0.5—Ersatz für Urotropin;" with the place, "Garnison-Lazarett Magdeburg."

A medical officer at the front, without books, without a pharmacist, obliged to decide in a hurry, knows what action he can expect from "urotropin" for instance, while the official name, indicating its chemical composition, has no concrete association in his mind with the clinical condition for which he wants the special action of the drug. Heubner adds that this has all been said a hundred times and just as often vehemently denied by the interested parties, but the fact remains that trade-marked names become in time the common name of the articles.

78. **Occupational Deformity of the Teeth.**—Kraus gives illustrations of a number of typical changes in the teeth induced by factors connected with the occupation. Candy-maker's caries is one. The sugar dust in the air settles on the teeth and the acids generated from the sugar eat away the enamel below. There is thus a shallow pocket hollowed out in the upper part of the front of each front tooth. Workers with hydrochloric acid display a characteristic irregular necrosis of the teeth, after a stage of brownish spots on the teeth. It is a molecular necrosis, beginning at the cutting edge and working downward. The teeth thus are soon gnawed away by the process. Workers on metal may develop a dirty green coating on their teeth which long persists if the teeth are not well cared for: Shoemakers may wear away a groove in the edge of the front teeth where they hold the peg or nail. The pronounced arch in the upper front teeth of glassblowers is readily explained by the tube they use, and the small groove in the front teeth of tailors and seamstresses by their habit of biting off the thread. The illustrations given confirm Kraus' statement that the changes in the teeth described are typical enough to indicate the occupation.

96 The Newer Medicinal Preparations and Foods Advocated in 1914 in Treatment of Tuberculosis. G. Schröder.
97 Tuberculosis in India. E. Wilkinson.

94. **How Apical Processes Originate.**—Hart presents an array of arguments to sustain his views regarding the mechanical predisposition to apical disease from stenosis of the superior aperture, to which Freund called attention long ago. Hart has encountered a number of young cadavers with marked anthracosis in the apex but no signs of tuberculosis. There was always something abnormal in the aperture, however, preventing free ventilation of the apex beneath; dust accumulates here although the tubercle bacillus has not happened to find a lodgment here. He has also encountered in a few cadavers an actual groove in the lung below the apex, a subapical pressure groove, but this is rare. He restricts the term phthisical thorax to the form with stenosis and deformity of the aperture. This is distinct from the thorax of general asthenia and also from the acquired paralytic thorax in the emaciated and cachectic.

The primary defective development of the aperture may be merely one localization of a more or less general physical inferiority. The manifestation at the aperture of this physical inferiority is liable to invite tuberculous disease of the apex; when manifested elsewhere it is liable to induce a predisposition to other affections, gastric ulcer, for example. Hence he thinks it is too sweeping to call this type of chest the phthisical thorax, as the individual with this form of chest does not inevitably develop tuberculosis. It would be more correct to call it the asthenic thorax or some similar term which would express that it is a primary manifestation of a constitutional tendency.

Zentralblatt für Gynäkologie, Leipzig

August 28, XXXIX, No. 35, pp. 611-626

98 *Exclusive Radiotherapy of Uterine Cancer. (Dürfen wir operable Uteruskarzinome ausschliesslich bestrahlen?) S. Flatau.
99 *Treatment of Inveterate Prolapse of the Uterus. O. Walbaum.

98. **Exclusive Radiotherapy of Uterine Cancer.**—Flatau has not operated on cancer of the uterine cervix since 1913. The proportionate number of women still living and cured under radiotherapy alone is larger than he could ever report before with abdominal operations for cancer of the cervix. It is now beyond question that an incipient cancer focus can be destroyed by radium without leaving a trace. But certain experiences have suggested the possibility that although the primary focus may thus vanish without leaving a trace, there is a possibility that metastases may develop at remote points, far beyond the scope of the rays. Time alone can tell whether radiotherapy will oust surgery from the arena of treatment. The surgeon and the radiotherapeutist can go on working, each in his sphere; in time comparison of the results will show which is superior.

99. **Treatment of Inveterate Prolapse of the Uterus.**—Walbaum makes a septum in the vagina as a support leaving two narrow channels each side which permit natural drainage of the uterus. The septum is made by joining the exposed bladder to the exposed rectum, the exposed area in each drawn up with circular stitches to provide a better hold. The perineum is also reenforced and sutured close up to the mouth of the urethra. He has applied this technic with most gratifying results in cases of extreme prolapse, primary or recurring.

106. **Functional Relations Between Thyroid and Suprarenals.**—Malovichko studied the changes in the suprarenals after removal of the thyroid, and vice versa. Of fifty dogs operated on for these studies eight succumbed; the rest were killed and the examination was done immediately afterward. It was found that after removal of the suprarenals, destructive lesions could be demonstrated in the thyroid in the form of degenerated epithelium, and changes in the colloidal substance and interstitial tissue. Removal of the thyroid together with the parathyroids does not seem to affect materially the suprarenals, but some fine structural changes in the cells could be demonstrated in them.

107. **Abdominal Fremitus.**—Schchetkin found abdominal fremitus in the right iliac region in patients suffering from chronic peritonitis with adhesions. This may be diagnosed clinically from the presence of this fremitus. The patient is asked to answer some questions and, while he is talking, the examiner's hand applied to the right iliac region experiences a manifest thrill or fremitus. He did not find this fremitus in acute peritonitis, or in any other abdominal affection, such as dropsy, but only in chronic peritonitis accompanied by solid connective tissue adhesions which transmit the fremitus of the diaphragm to the right iliac region.

108. **Cultivation of Leukocytes Outside of the Body.**—Avroroff and Timofejevsky succeeded in cultivating white blood corpuscles outside the body according to Carrel's method. The mononuclears of normal blood they found are able in the mediums to proliferate through karyokinesis, and to become transformed into different shapes, such as hypertrophied, giant and protoplasmic cells. This ability of the mononuclears to undergo such changes confirms the theory of their active rôle in the healing and regeneration of tissues with transformation into different forms such as polyblasts and giant cells. Cultivation experiments may thus shed further light on the question of the origin of the eosinophil granules. This article is illustrated.

113. **Treatment of Trypanosomiasis.**—Of various remedies used by Yakimoff for treatment of mice injected with trypanosomes from camels and donkeys in the Turkestan region, he found salvarsan and antimony trioxid most effective.

114. **Poisoning from Substitutes for Liquor.**—Yakovleva had the opportunity of examining eighty patients poisoned with cologne water, denatured alcohol, furniture polish, varnish or similar substitutes the patients had been using in the place of ordinary liquor. The general symptoms of denatured alcohol poisoning are depression instead of excitation of the nervous system, pain in stomach and chest, and vomiting. In addition there was amblyopia which usually set in rapidly in a few days or weeks, with great impairment of visual acuity, frequent appearance of absolute central scotoma and concentric narrowing of the field of vision. Poisoning from wood alcohol and eau de Cologne gave the same symptoms as described in the literature from methyl alcohol poisoning. Here frequently occurs a secondary aggravation of the impairment of vision, following a temporary improvement. Another peculiarity of methyl alcohol poisoning is its cumulative action—the symptoms of poisoning developed only after repeating the dose, usually the next day. The details of the eighty cases are tabulated in full, filling three large pages.

115. **Periodical Vomiting.**—Nikulin calls vomiting periodical when it occurs at the end of the so-called periodical activity of the gastro-intestinal tract. This activity, in the form of contractions of the stomach and intestines, secretion of pancreatic juice, bile, etc., is periodically followed by stages of rest during which no secretion and no peristalsis take place. Nikulin studied the occurrence of periodical vomiting in a dog, the vomiting recurring nine times. He reports that the vomiting usually started at the end of the "period of activity or work of the stomach, and it never occurred during the period of rest." During the vomiting the quantity of intestinal secretions—which contain intestinal and pancreatic juices and bile—is increased, twice or three fold, proportional to the motor power. It is evident that the motor and secretory properties are intimately connected, the increase of one causing the increase of the other. The total amount of ferments in the gastro-intestinal contents is increased during vomiting, proportional to the amount of the intestinal mixture. Periodical vomiting has been observed in pregnancy. It displays here some of the features he found in his experiments on the dog. The Abderhalden reaction was found positive with the serum during the period of work, and negative during that of rest, indicating an increased flow of ferments into the blood. When this increase is too great, the body tries to get rid of the superfluous amount of ferments through vomiting, which is thus periodical in character.

116. **Umbilical Cord as Patching Material.**—Perimoff describes two cases in which umbilical cord was used to cover the defects in mucous membranes (scar between upper and lower jaws, and fistula under the lingual bone). The results were excellent. His previous experiments along the same line were summarized in these columns, August 14, p. 658.

118 *Roentgen Treatment of Cancer. (Om Røntgenbehandling af ondartede Svulster.) S. and J. Nordentoft.

118. **Roentgen Treatment of Malignant Tumors.**—Nordentoft reports the further course in twenty-four cases of cancer in which courses of Roentgen treatment were applied one or more years ago. He emphasizes that a person who has had a cancer removed, or cured by other means, must keep in touch with his physician afterward, realizing that he must be kept under sharp observation for all the rest of his life. Nordentoft makes a point of continued supervision, and publishes from year to year the present status of the more interesting cases, omitting superficial cancers and recurring mammary cancers. In this communication he presents evidence that cancer of the mouth and tongue may yield surprisingly quickly to Roentgen treatment, also that metastases of malignant disease are liable to retrogress under the Roentgen rays.

The series reported here include only the cases in which Roentgen treatment has conquered new fields, namely cancer starting in the mucosa of the mouth or vulva, or deep-seated cancer, as in the pelvis, abdomen, chest or brain, or cancer of the esophagus or rectum. Even in the absolutely hopeless cases, marked benefit was apparent for a time. This was particularly striking in a case with metastasis in the lungs from cancer elsewhere. Among the patients still in good clinical health are one man of 45 with a sarcoma in the mediastinum (the last course of Roentgen treatment was given in 1911); one woman of 64 with recurring cancer of the vulva (last treatment 1913), and several with cancer of the mouth. He also gives the details of cases which proved absolutely refractory to the rays, including one of cancer of the lung. The necropsy findings are also given in the cases that have terminated fatally after the Roentgen treatment or the patients have succumbed to intercurrent disease. The cases are listed serially for this report. The following yearly communications will carry on the history of each surviving patient under the same serial number. In time the data thus accumulated for each individual case, as the years go on, will supply a basis, by comparison, for general conclusions as to the efficacy and technic of roentgenotherapy in malignant disease. He urges others to carry on similar series, reiterating that a patient cured of cancer should never be allowed to forget the need for perpetual medical supervision to detect recurrence or metastasis in its incipiency.

SOME ASPECTS OF OPHTHALMIA NEONATORUM *

GEORGE S. DERBY, M.D.
BOSTON

This paper is based principally on a series of 149 cases of ophthalmia neonatorum under my charge in the contagion wards of the Massachusetts Charitable Eye and Ear Infirmary, between Aug. 1, 1913, and Oct. 1, 1914. It is not presented primarily, however, as a statistical study, or as a consideration of the whole subject of ophthalmia neonatorum, but rather of those aspects of the disease which have appealed especially to me and about some of which there is yet considerable difference of opinion. In addition, attempt has been made to bring the sociological aspect of the disease into close relationship with the clinical side.

HOSPITAL OR HOME TREATMENT

In the first place, is a baby with a severe ophthalmia neonatorum best treated in the home or in the hospital? The obvious answer is, at the hospital, if we exclude those cases occurring in well-to-do families in which it is possible to employ a capable ophthalmologist and at least one skilful nurse. Sydney Stephenson,[1] however, states that he never takes a baby into the hospital unless loss of sight is imminent, as it is not wise to wean a baby with this disease if it can possibly be avoided. Stephenson is by no means alone in this opinion. The importance of this statement must be readily appreciated when we realize the impossibility of obtaining proper ophthalmic nursing in the average family in which this disease occurs, and the great and apparent danger to every other member of the household.

Such a statement is extremely significant and can mean only one thing, that the usual hospital treatment provided for this disease is unsatisfactory, that the advantages of skilful treatment of the eyes, which, it goes without saying, all ophthalmic institutions can offer, are offset by the lack of that specialized care which is so necessary in the early days of life, and more particularly in those instances in which it is absolutely necessary to wean the infant.

The reason for Stephenson's statement lies in the fact that the mortality in cases of ophthalmia neonatorum treated in the hospital is usually extremely high. Furthermore, in many cities suitable accommodations are not provided. For instance, Holloway,[2] in a recent paper on ophthalmia neonatorum, states: "The Philadelphia hospitals have largely avoided the admission and treatment of these cases. . . . No accommodation is provided for them in the only hospital in Philadelphia devoted exclusively to diseases of the eye."

Harman,[3] in his study of the statistics of cases of ophthalmia neonatorum occurring in London in 1911, states that the general and ophthalmic hospitals had difficulty in providing for these cases. "Of the cases occurring in the practice of midwives during the year, in twelve instances mother and child were admitted to hospitals or infirmaries, and in twenty the child alone was admitted; 101 other cases were treated by the ophthalmic and general hospitals as outpatients." This series comprised at least 278 cases; the exact number is not given.

This does not mean, however, that ophthalmia neonatorum is best treated in the home, but rather that in general the hospital treatment is unsatisfactory and often difficult to obtain.

To my mind there is but one answer to the question originally propounded. In the vast majority of severe cases, ophthalmia neonatorum should be treated in the hospital, for it represents an extremely contagious disease, dangerous to the eyesight, and produces a very large amount of visual loss. It is also my contention that these cases can be handled in the hospitals with comparative safety; that is, the mortality among them will be little greater than the normal mortality among infants in the first year of life, always taking into consideration the fact that infants affected with this disease average below normal in their general vitality and that they are subjected to unusual conditions, in that the eyes must be cleansed very frequently, thus necessitating frequent handling, which would be deleterious to any normal infant. This handling, however, would be less likely to do the child harm if carried out by a nurse skilled in the care of babies than by the less skilful attendant in the home.

MORTALITY

Our figures, such as they are, tend to substantiate the views expressed. In 149 cases occurring during fourteen months, 6 babies died in the hospital. Two of these were premature, 1 died of meningitis, 1 of pneumonia and 2 of hemorrhagic disease of the new-born.

To arrive at the true mortality, however, cases should be kept under observation for a year. Of 124 cases of our series admitted between October, 1913, and October, 1914, it was possible to follow the course in 81. Of these, 3 patients died in the hospital and 4 died after their discharge. Assuming the same mortality for the 43 who could not be followed up as for the 78 (81 — 3) that could, we should expect, at the most, 3 more deaths among these, which would give a total number of 10 deaths in 124 cases (80 deaths per 1,000), an extremely good showing, and comparing favorably with the infant mortality of the city of Boston for 1914, about 103 per 1,000, which in itself was a low figure.

[3] Harman, N. Bishop: Incidence of Ophthalmia Neonatorum in London, Brit. Med. Jour., 1913, p. 1099.

Figures showing mortality in this disease are hard to obtain and are often misleading. One of our patients is of interest in this connection, a premature twin with gonorrheal ophthalmia. The eyes of the second twin were normal. The child was admitted to the hospital, the disease treated, and it was discharged from the hospital on the fiftieth day after birth. It died at home one day later, although it seemed in good condition when it was discharged. The other twin had died eleven days earlier. In spite of the handicap of the eye disease, it seems as though this child's life may have been prolonged rather than shortened by its stay in the hospital.

Among the well-to-do, with whom skilled nursing and medical attendance are a matter of course, mortality among babies having ophthalmia neonatorum must necessarily be higher than the normal mortality among babies in the same social condition. In infants of the poorer classes, however, if they be admitted to a suitably equipped hospital, the more scientific care which they receive should be enough to offset the handicap of the ocular disease, and the mortality should not be higher than the normal, and perhaps even less. It goes without saying that the most important single factor is the feeding, and to this I shall return.

An adequate system of charts and records is of great importance, so that the visiting physician may see at a glance the essential features which can be recorded about each case. A copy of our chart is appended, the general features of which we owe to Dr. F. B. Talbot of the Massachusetts General Hospital and formerly our consulting pediatrician. The credit of introducing modern and systematic methods of caring for these babies in the infirmary is largely due to him. The part of the chart relating to eyes was worked out by Dr. C. T. Porter, recently an intern in charge of these cases. This chart shows at a glance the temperature, pulse, respiration, gain or loss in weight, character of the stools, number, amount and character of feedings, number and character of eye treatments, the bacteriologic record, and the condition of the corneas at entrance and discharge.

Chart of Massachusetts eye and ear infirmary.

In regard to feeding, it was only in March, 1914, that permission could be obtained from the hospital authorities to admit the mothers of these babies whenever possible. This is now being done. In frequent instances, when the mother is unable to come permanently into the hospital, she can often come twice a day to nurse her baby. At present about two thirds of our babies receive at least part of their nourishment from maternal sources. When the mother is sick and cannot come, it is frequently possible to obtain breast-milk from her, and finally, in those cases in which the maternal milk is not available and breast-milk is a necessity, it is obtained from other institutions. For bottle-fed babies the best certified milk is provided, and the mixture is prescribed by the consulting pediatrician, who makes a regular visit twice a week and is on call at all times.

No one can deny that these babies are subjected to unfavorable conditions, for in some of our most severe cases it is necessary to cleanse the eyes every half hour during the twenty-four, and it is impossible to expect a baby to thrive under these circumstances. Here is where a question of the nicest judgment comes in; on the one hand, the eyes need the most frequent and careful cleansing, on the other hand, the premature or sickly infant needs warmth, quiet and as little handling as possible. No general rule can be laid down, except that it is probably best to err in favor of the general condition. Treat the eyes as infrequently as is consistent with safety. Watch the baby's weight. If the baby is losing ground, reduce the eye treatment even to once every three or four hours (when possible). If the baby is in good condition and stands the frequent handlings well, we may cleanse the eyes as often as is required by the severity of the disease, as shown by the amount of discharge and by the corneal conditions. Treatments of the eye, when this is possible, should never be carried out directly after a feeding, for in many instances the feeding will be regurgitated. Treat the eyes directly before the feeding, and then wait as long as possible. In the same way, the visits of the attending ophthalmologist should have regard to the time of feeding.

Finally, it should be repeated that in the zeal for frequent treatment the resisting ability of the baby must be remembered. Constant handling reduces this. The conjunctival discharge, as has been shown in a number of our cases, will persist for weeks in babies of low vitality in whom every known device of local treatment has been tried. Under careful observation as to the condition of the cornea, reduce the local treatment to once every three or four hours, and not infrequently an improvement will be noticed. The patient will begin to gain weight and the conjunctivitis will gradually subside.

PREMATURITY

Turning from the more general features of the disease, it may be of interest to take up some of the special points on which our series throws some light. Stephenson and other writers give prematurity as the chief general predisposing cause of the disease for three reasons: (1) less resistance, (2) thinness and delicacy of conjunctiva, and (3) lack of the vernix caseosa.

Just how important prematurity is in the etiology of our cases is somewhat difficult to determine. According to the information obtained from the parents and attendants in our cases, 17 were premature. In 9 of these the gonococcus was found in the ocular discharge. The weight was recorded in 110 cases; 16 patients were under 5 pounds and 11 more between 5 and 6 pounds.

MONOCULAR INFECTION AND PROTECTION OF THE SOUND EYE

Various writers say that ophthalmia neonatorum, as a rule, eventually become bilateral, though at the same time unilateral cases cannot be regarded as exactly rare. Statistics show monocular infections varying in percentage between 5 per cent. of 100 cases reported by McKenzie and Marshall, and 25 per cent. of 868 cases reported by Cohn.

In our series of 149 cases, 77 were definitely due to the gonococcus. Of these, 18 were monocular and remained so, a percentage of 23.4.

Forty-four infants out of 75 cases in which we have records on this point developed the disease in both eyes on the same day. Of the remaining cases, 18 infants developed the disease in one eye only, and of these, 8 showed evidence of conjunctivitis within three days after birth, while 10 developed it on the fourth day or later, 2 on the fifth day, 3 on the sixth, 1 on the ninth, 2 on the tenth and 2 later than ten days. It seems probable, therefore, that over one half of the monocular infections in this series were secondary and not acquired at birth. Of the remaining 13 cases the interval between the appearance of conjunctivitis in the two eyes was as follows: 11 within four days of the appearance in the other eye, 1 on the tenth day and 1 later. In no one of our cases did the infection of the second eye occur after admission to the hospital, a tribute to the efficiency of the nursing force.

The precautions taken to avoid infection are simple. The child should lie on the infected side; its hands and arms should be confined, as is the usual hospital practice with young babies; and a drop or two of protargol or argyrol may be put into the healthy eye two or three times a day. I am inclined not to attach so much importance to this last measure as to general cleanliness. The main precautions are those to be taken by the nurse. That infection does not take place is entirely due to her ever-watchful care.

BACTERIOLOGY

Occasionally an infant or adult comes to the hospital presenting the signs of a conjunctivitis, and under the microscope we find extracellular and intracellular gram-negative organisms corresponding in their morphology to the gonococcus. The patient is admitted to the wards and energetic treatment instituted, with the result that at the end of a week the eyes are nearly normal and the patient nearly ready to be discharged. Under the system of smears alone, the case would be regarded as a gonorrheal conjunctivitis.

To obtain accurate results, steps should be taken in every hospital to separate the gonococcus from the other gram-negative, biscuit-shaped diplococci, the most important of which group, from our standpoint, is the *Micrococcus catarrhalis.* This cannot be done by smears alone, and thus cultures should be taken, as the *Micrococcus catarrhalis* grows on ordinary mediums and the gonococcus does not.

In each of our cases, before admission to the hospital, two smears are now taken and several cultures made on blood serum and on hydrocele agar. The statistics shown by our cultures and smears are not of particular interest except for a few facts. From the present series, cultures were taken in 125 cases, and the *Micrococcus catarrhalis* (or some other gram-negative diplococcus, not the gonococcus) was grown three times. This shows a source of error, small but worthy of note, as Axenfeld first pointed out.

The gonococcus was found in seventy-seven of our 149 cases of ophthalmia neonatorum, and the clinical picture was characteristic. This gives a percentage of only 51.3, considerably lower than the usually quoted two thirds of all cases.

Of 1,829 cases collected by Stephenson, 65 per cent. showed the gonococcus. In but few of these, however, were careful bacteriologic examinations made and other gram-negative diplococci excluded. This figure is probably too high.

Bartels,[4] in a series of 70 cases, in which the bacteriology was carefully worked out, found gonococci in thirty-eight, or 54 per cent. He believes the gonococcus is the etiologic factor in about 50 per cent. of cases.

The striking fact, however, in my series is the presence of 56 cases in which no organisms whatever were found in the smear, although two smears were always examined, and in the case of a negative result, often several more. In several of these negative cases

---

[4] Bartels: Klin. Monatsbl. f. Augenh., 1911, Part 1, p. 557.

41 cases; Haupt, 28 per cent. of 45 cases; Kroener, 25 per cent. of 62 cases; Druais, 25 per cent. of 24 cases.

Harman[3] found in a series of 231 cases of ophthalmia neonatorum of all degrees of severity, and nongonorrheal and gonorrheal cases combined, 13 cases of corneal damage, 5.6 per cent. Of the 13, 3 were blind in both eyes and 5 more blind in one eye.

In my series of 77 cases in which the gonococcus was found in the secretion, 5 patients were discharged with damaged cornea, a percentage of only 6.5.

All our patients with corneal damage have been carefully investigated, and when possible, steps have been taken to bring the guilty party to book. One physician has been prosecuted and found guilty, but appealed, and the case is not yet settled. One midwife was forced out of practice, but no further penalty was inflicted in view of her advanced age (84). One midwife was educated in her duties. In the others, either no ground for prosecution was found, or the difficulties were so great as to make conviction seem impossible. The results of this endeavor to place the responsibility are not brilliant in this series, but this method undoubtedly forms one of the most potent weapons in preventing loss of sight from this disease. It should be remembered also that in Massachusetts we are working under very favorable conditions as compared with all but a very few of the other states, as we have a good birth-reporting law and an effective law for the reporting of ophthalmia neonatorum. Moreover, we have an active Commission for the Blind, which has made it its business to see that these laws are enforced. What is needed next is greater control by the State Board of Health over the local boards, since these local boards vary greatly in efficiency.

LOCAL TREATMENT

The local treatment of ophthalmia neonatorum has occupied a large share of the attention of writers on this subject. There is nothing to be added to what has been said many times over, and indeed, no advance in this direction is to be expected until some specific drug or serum is discovered.

Various antigonococcus serums and vaccines have been used in the past, but on the whole the results have been indifferent. The latest of these, the vaccine of Nicolle and Blaizot, although heralded as a great advance, has hardly borne out the claims of its adherents. Among others, it has been used by Morax, who reports a favorable influence on the disease in a few cases and no influence in others. He would only advise employing it as an adjunct to the regular treatment with the silver salts.

In our cases the eye is cleaned as often as necessary to keep it reasonably free of pus, be it every twenty minutes or every three hours. The lids are wiped clean and then separated with the fingers; the conjunctival sac is washed out with boric acid squeezed from a pledget of cotton, several drops of one of the milder silver salts are instilled, the excess wiped away, and the lids are liberally smeared with some bland salve, such as White's ointment or boracic ointment. Injury to the corneal epithelium is most carefully guarded against. In the later stage of the disease, if the conjunctiva becomes boggy and little improvement is taking place, silver nitrate and zinc sulphate are called into use.

Regarding the silver preparation to be used in the acute stages of the disease, I believe that a nonirritating drug is indicated; that the stronger silver preparations, such as nitrate, do good in inflammations by their ability to set up a reaction and draw in protective substances from the neighboring tissues; and that their place is therefore in those inflammations in which a sufficient reaction does not already exist. This is not the case in gonorrheal ophthalmia, since the reaction is often too great (especially in the adult form) for the conjunctival circulation to take care of. Bactericidal power is of little importance, as the gonococci lie too deep to be reached by any remedy which we have yet at our disposal, and since, as I among others have shown, the germ-killing power of even the stronger silver preparations is markedly impaired as soon as they come in contact with the tissue proteins. Argyrol is, at the most, a very weak bactericide to start with.

In the present series argyrol 25 per cent. has been used almost exclusively. Probably protargol in weak solution, 2 per cent. or 4 per cent., would be equally efficacious, although its specific gravity is not so high. The controversy over the merits of the various silver salts has waged long and has not arrived at a final settlement.

For the reasons stated above, I believe that in the acute stages of the disease a mild remedy is indicated. The high specific gravity of argyrol, 25 per cent. (in the neighborhood of 1.070), may be of value in its cleansing action; it is surmised that it tends to float the pus out of the hollows of the conjunctival sac. A manifest advantage of such a solution, and one to which I have not seen reference, is the early warning given of a break in the corneal epithelium by the immediate staining of the area involved.

It is not improbable that in the past harm has been done in this disease by the use of too strong applications. It would seem that the virtue of the milder ones lies partly in their negative qualities.

It should be expressly stated, however, that the foregoing remarks apply solely to the treatment of ophthalmia neonatorum, and not to its prophylaxis, in which the nitrate is supreme.

Before discharge of gonorrheal patients from the hospital, two negative smears at an interval of twenty-four hours or over are required.

ABSTRACT OF DISCUSSION

Dr. Joseph L. McCool, Portland, Ore.: It seems to me that the best way to handle ophthalmia neonatorum depends largely on the locality in which one practices. Those of us who live on the Pacific coast do not see as many cases as do our colleagues in the East, for we do not see so much poverty and wretchedness. Furthermore, the demand being insignificant, our facilities are inadequate for the proper handling of these cases. In view of these facts it seems to me that so far as we are concerned these cases can be treated best at home with, of course, as careful instructions as we can give to those in whose care they are placed.

In considering the subject of prophylaxis, I was surprised to learn from several of our most prominent physicians whose obstetric experience is large that there is a lack of uniformity in the application of the Credé method; some of them use it only occasionally. This is to be deplored, as there can be no compromise on this question. It should be used in every case. In educating the public to report this disease, it is well to remember that we can get better results if we assure them that a large percentage of these cases are not gonorrheal in origin and should not be concealed from any sense of shame. This, I believe, was pointed out by the late Mark D. Stevenson several years ago. Dr. Derby's application of the complement-fixation test to these cases is very interesting and original, and again emphasizes the fact that it is a mistake to regard gonorrhea as a purely local disease. I am inclined to agree with the essayist in the use of mild cleansing solutions used at frequent intervals and, despite the poor bactericidal value of argyrol, to follow with the liberal use of this silver salt.

Dr. W. H. Roberts, Pasadena, Calif.: I would like to ask Dr. Derby if he has any figures showing in what proportion of cases in which ophthalmia neonatorum develops, the Credé method has been employed?

Dr. H. H. Stark, El Paso, Tex.: Dr. Derby has called to my attention a point that I have overlooked in the treatment of clinical cases. I have probably the worst class of clinical cases of any man here, all Mexicans of the lower class, people without any means, very little education and hard to control. I have probably had in the last five years between eight and ten thousand cases in the clinic; of these, a hundred to a hundred and twenty-five were cases of ophthalmia neonatorum. These cases no doubt represented only a small per cent. of the cases in our community. Those of you who are acquainted with Mexico know of the prevalence of blindness which occurs in childhood. This blindness in the majority of cases is due to this disease. It is impossible to put these patients in the hospital as the mother will not go, neither will she permit her child to go. Consequently one must rely on the treatment given at home. We therefore have adopted a routine treatment consisting of 2 per cent. nitrate of silver solution every other day, in the clinic, argyrol at home several times a day, and a wash of 1:5,000 permanganate of potash. With the use of this medicine I doubt if the child's eyes are ever opened and washed out with the permanganate solution, for it is a common thing for patients with eye trouble to come in several weeks after beginning treatment and ask for permission to wash their faces. It is an exception to have a patient admitted to the clinic in whom the cornea is not clouded. But with this inefficient treatment it is seldom that we lose an eye. Consequently I think there may exist an immunity, as suggested by Dr. Derby Recently we have proved in our clinic that there exists an immunity against syphilis, by having the Wassermann test done on fifty patients, thirty men and twenty women, complaining of no especial ailment other than minor ills, in which we found a uniformity of 65 per cent. positive. I therefore believe there may exist a partial immunity in the children against the eye infection.

Dr. Charles L. Williams, Topeka, Kan.: I have gained some valuable information from Dr. Derby's paper. I would like to say, however, that I believe in treating these patients only in a hospital. My only bad results have been when I left the patient in the home with or without the nurse. There is too much responsibility resting on the ophthalmologist to allow these patients to be anywhere except in the hospital. They are too important. I insist on the mother going there with the child. I do not use anything except the nitrate of silver, 1 grain to the ounce. It will do the work if properly used. It is to be used twice a day, and the main part of the treatment is flushing the lids. Keep the secretions thoroughly washed away by irrigations every half hour if necessary. After that applications of ice, to reduce local temperature, are comforting to the patient and retard the infection.

Dr. Edward Jackson, Denver: After seeing Dr. Derby's work in his hospital, as I did a few months ago, I was impressed with the idea that he had there worked out nearly an ideal method of treating ophthalmia neonatorum, with the hospital facilities he had and his ability to bring in the mothers at least two or three times a day to nurse the infant if not kept there all the time. But for that line of treatment you must have the hospital, together with those facilities, and so organized. A great many of these patients will have to be treated without those facilities. There should be a distinction made between the treatment under the circumstances Dr. Derby has set forth, and under other circumstances that a great many men will have to contend with.

With the child in the hospital and with efficient, experienced nurses in charge, there is no reason, certainly not in the great majority of cases, for resorting to silver nitrate or other strong applications. Regular and thorough cleansing is all that is necessary. But if the patient must be left with the parent or nurse in the home for several hours, and sometimes without the care of a nurse, then I believe the use of the silver nitrate cannot be given up. The bad results I have seen have all been due to repeating the applications too frequently. I do not refer to the weak solutions, say 1/10 grain to the ounce, but to 2 or 4 per cent., which is perhaps strong enough to use in any case. If such a solution is to be used it should be applied not more often than once in two days, or perhaps once in twenty-four hours. This, with careful cleansing, is the best thing that can be depended on in home treatment. Strong solutions I have seen used as often as once in six hours, and such treatment is certain to be followed by serious results.

Dr. Robert W. Miller, Los Angeles: Unquestionably one of the most important things is prophylaxis, and I trust that the ophthalmologists will continue to insist on prophylactic measures and work through the proper channels persistently and systematically to secure that end. I would not refer to the use of concentrated silver nitrate solutions but for the fact that I have met within the last few months a number of very capable ophthalmologists who still defend their use and employ them. The one thing we wish to avoid is corneal involvement. To my mind the use of concentrated nitrate of silver solution tends to invite corneal infection by damaging or destroying the epithelial layer. Previous statistics have indicated pretty clearly that we cannot rely on any known drug or chemical agent for the destruction of the gonococci in the deeper portions of the connective tissue. The better plan is to wait and let nature conduct, as well as she can, her campaign against these invading bodies. The keynote consists in constant, gentle cleanliness. We have had many conflicting reports in regard to the action of argyrol. Its manufacturers have told us that it is bactericidal. Others have told us it has no bactericidal effect whatever. Bruns, of New Orleans, reported a few years ago having employed argyrol in a series of cases with very gratifying results. The point of vital importance is the continuous "flooding" of the cornea and conjunctival sacs, with the 25 per cent. argyrol solution. I have had an opportunity of using it in a number of cases and have been well pleased with it. I do not speak against the use of nitrate of silver entirely. I admit its value in certain cases. I speak only against the concentrated solution, that may prove harmful to the eye.

Dr. E. C. Ellett, Memphis, Tenn.: In regard to the method of prophylaxis, I do not think we should countenance any modification of the Credé method. This should not be taken to mean that there are not other methods which are quite satisfactory, but if we present a solid front on this point it would avoid any confusion in the minds of those who are guided in these matters by the experience and advice of others, and would result in placing the responsibility for the occurrence of these cases where the responsibility belongs.

Dr. George S. Derby, Boston: I must take issue with Dr. McCool, in that I do not think it is safe to handle these cases in the home unless one has a nurse. This disease needs skilled nursing more than any other feature. More injury to the cornea is done by scratching the epithelium with the nail than in any other way. I believe it would be difficult to work out the statistics of disease after treating by Credé's method. That question is best determined by statistics obtained from the lying-in hospital.

In regard to what Dr. Williams said, I would simply like to repeat what I said concerning the value of argyrol. In addition, it is nonirritating, which is a great advantage, and secondly, it will bring to your attention a break in the epithelium when it first occurs. In reply to the question why we do not use nitrate of silver in the sound eye, I can say that under our present method of treatment the sound eyes do not become infected. Argyrol is much less irritating and we do not see the necessity of putting in a drop of silver when the argyrol does just as well. In Massachusetts the law requires physicians to report all cases of ophthalmia neonatorum immediately. One hesitates to disagree with Dr. Jackson, but after what I have seen of the treatment of ophthalmia neonatorum, I cannot help but feel that nitrate of silver is contraindicated. I do not believe nitrate of silver works as a bactericide. It does good by setting up a reaction. In diseases of this kind you have a marked reaction and you do not ned any more. Treat it mildly and you will get on better than if you put in stronger drugs. I believe thoroughly in 1 per cent. of nitrate of silver as a prophylactic.

A DISCUSSION OF THE CANCER MORTALITY

FREDERIC V. BEITLER, M.D.
Chief of the Bureau of Vital Statistics, State Department of Health of Maryland
BALTIMORE

In discussing the cancer mortality there are a number of questions which should be considered with it. While the figures which I have used are, within the limits of slight error, correct, such questions as the relation of improved methods of diagnosis to the cancer mortality, or the relation of changes in the composition of the population to the cancer mortality, must be given proper consideration in the final analysis of any cancer statistics. Whether or not these questions are factors of importance in the mortality rates of cancer is, at present, more or less a matter of personal opinion, and will remain so until through some laborious investigation their exact status will be determined.

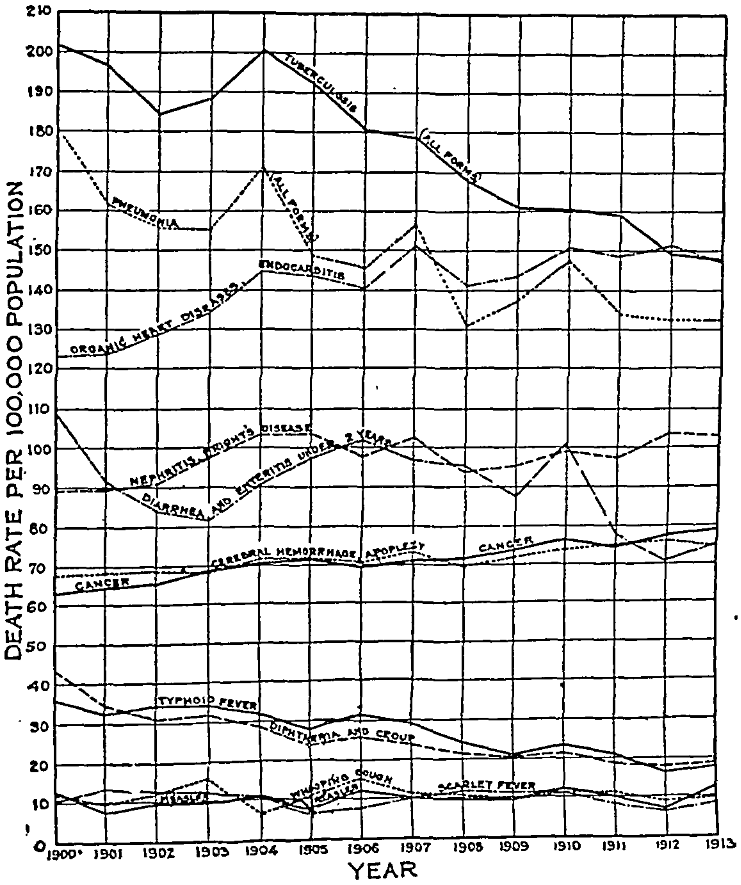

Chart 1.—Deaths per one hundred thousand from cancer and other causes, 1900 to 1913 (mortality report, census bureau).

The population figures used here were compiled from the reports of the census bureau, and the mortality figures were all taken from the report of the Division of Vital Statistics of the Census Bureau. That the mortality reports were drawn from a large portion of the population of the United States is evidenced by the fact that the registration area for deaths represented 40.50 per cent. of the population of the United States in 1900, and 58.30 per cent. in the year 1910.

In order to obtain sufficient material for several of the tables, I was compelled to confine the figures to those for the registration states, which does not include quite the population of the registration area. In the year 1900 they include 40.48 per cent. of the population of the United States; in the year 1910, 51.37 per cent. of that population. The figures and rates have been carefully compiled, and in no single year give divergences which would be considered unusual. Without further discussion at this time I will give the result of a survey of the cancer mortality for ten years in the registration area. In the registration area for the year 1913, there were 49,928 deaths from cancer. Assuming that cancer is as prevalent in that portion of the population not included in the registration area, the total deaths in the year 1913 would be 76,694.

TABLE 1.—REGISTRATION AREA OF CANCER FOR PERIOD 1904-1913

Year	Deaths	Per Cent. of Total Deaths	Mortality Per 100,000	Estimated Population
1904	23,395	4.24	70.15	33,349,137
1905	24,330	4.46	71.36	34,094,605
1906	29,020	4.41	69.12	41,983,419
1907	30,514	4.44	70.93	43,016,990
1908	33,464	4.84	71.52	46,789,913
1909	37,562	5.13	73.84	50,870,518
1910	41,039	5.10	76.22	53,843,896
1911	44,024	5.25	74.27	59,275,977
1912	46,531	5.55	77.01	60,427,247
1913	49,928	5.60	78.88	63,298,718

In reviewing the cancer mortality over a ten-year period, from 1904 to 1913, inclusive (Table 1), a steady increase is noted in all years except the year 1906. In the year 1904 there was a mortality of 70.15 per one hundred thousand; in the year 1913 it had increased to 78.88 per one hundred thousand, a gain of 8.73 per one hundred thousand in a ten-year period. This represents an increase of 12.47 per cent. in the cancer mortality per one hundred thousand for a ten-year period. The relation of the cancer mortality to the general mortality during the same period shows a corresponding increase. In the year 1904 the deaths from cancer represented 4.24 per cent. of the total deaths, while in the year 1913, 5.60 per cent. of all deaths, an increase in its relation to the general mortality of 32.07 per cent. The cancer mortality in this ten-year period, both in its relation to the general mortality and in its relation to the population, shows, except in the year 1906, a steady increase. This increase is graphically illustrated in Chart 1 (taken from the mortality statistics of the census bureau), and for a fourteen-year period shows a gradual rise in cancer deaths. The decline of the death rate in several of the major infectious diseases, namely, tuberculosis, pneumonia, typhoid fever, diphtheria and croup, stands in contrast to the cancer mortality.

SEX DISTRIBUTION

If our figures show an increase in cancer deaths, it would be pertinent to inquire into the distribution of this increase in the male and female portions of the population (Table 2).

A glance at Table 2 shows that cancer is more frequent in females than males. In the year 1904 cancer deaths in males constituted 1.61 per cent. of the total mortality; in the year 1913, 2.25 per cent., an increase of 39.75 per cent. in its relation to total deaths in ten years. In the female population for the year 1904 the cancer mortality constituted 2.63 per cent. of the total mortality, and in the year 1913, 3.35 per cent., an increase of 27.38 per cent. in the decennium. Comparing the percentage of increase in males and females in relation to the general mortality, we have in the male population an increase of 39.75 per cent., and in the female, 27.38 per cent.; an 11 per cent. excess increase in the male population.

This change in the distribution of the cancer mortality is strikingly shown by comparing in Table 2 the percentage of cancer deaths that occurs in the male and female population. In the year 1903, 37.96 per cent. of all cancer deaths occurred in the male population, while 62.04 per cent. of the cancer mortality occurred in the female population, and ten years later, 1913, 40.15 per cent. of the cancer mortality occurred in the males and 59.85 per cent. in the females. It appears here that the pendulum of cancer mortality is slowly swinging out of the female and into the male population. This is graphically shown in Chart 2. The lower line over the double cross-hatching represents the percentage that the cancer mortality in male and female population bears to the total mortality, and the upper line over the single cross-hatching indicates the percentage of cancer deaths in males and females by years.

There can be little argument regarding the correctness of this particular phase of cancer mortality. This is a discussion of the distribution of cancer deaths in two divisions of the population, and no matter what the relation of other conditions be to the general cancer mortality, it could not affect, to a great extent, figures whose basis of comparison is entirely within the cancer deaths tabulated.

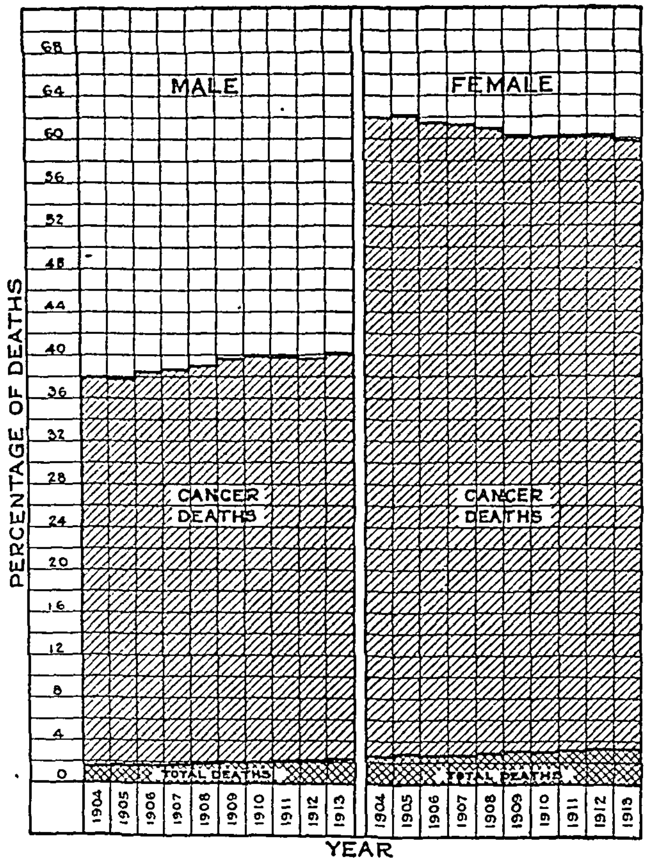

Chart 2.—Relation by sex and year of cancer deaths to total deaths, and the distribution of the percentages of cancer deaths in the male and female population.

AGE DISTRIBUTION

It was necessary, in order to obtain accurate population figures in the table showing age distribution of cancer, to confine the data to that obtained from the registration states. I also purposely constructed these tables from the data for the years 1900 and 1910, which, being census years, would add to the accuracy of the tables in their respect to the population figures.

The age distribution of cancer is now and has been one of the most interesting phases of cancer mortality. Whether or not cancer is more frequent at earlier or later ages has been a matter of conjecture for some years. The changes in the age distribution of cancer and its bearing on the mortality can only be discerned by proper statistical investigation..

In Tables 3 and 4, we have the age distribution and mortality for the years 1900 and 1910. By referring to these tables it will be noticed in the year 1900 that 10 per cent. of the total cancer mortality occurs prior to the fortieth year, and that in the year 1910 about 9 per cent. of the cancer mortality occurs prior to that age.

The number of cancer deaths at various age periods, however, does not indicate properly the age distribution of cancer. It has been a common error for persons inter-

TABLE 2.—DEATHS FROM CANCER, REGISTRATION AREA, 1904-1913; PER CENT. OF TOTAL DEATHS IN MALES, PER CENT. OF TOTAL DEATHS IN FEMALES, AND PER CENT. OF TOTAL DEATHS *

Year	Male Deaths from Cancer	Per Cent. of Cancer Deaths	Per Cent. of Total Deaths	Female Deaths from Cancer	Per Cent. of Cancer Deaths	Per Cent. of Total Deaths	Total Cancer Deaths	Per Cent. of Total Deaths
1904	8,881	37.96	1.61	14,514	62.04	2.63	23,395	4.24
1905	9,189	37.77	1.68	15,141	62.23	2.78	24,330	4.46

---

* Assuming the population of the United States to be constant for the next ten years, and the general death rate to average that of the registration area for the period 1904-1913 (15.06), at the present rate of increase of cancer deaths, would give in the year 1923, a surplus of 19,819 deaths from this cause, making a total of 101,427 deaths for the year.

† Estimated population of the United States in 1913, 96,765,573.

preting statistical tables to pay too much attention to percentages in analyzing the age distribution of deaths, for the real measure of the true mortality at any age period is found in the specific rates for that age period. In examining the specific rates for cancer for the two years, 1900 and 1910, it will be found that up to the fortieth year there are no marked increases in the mortality rates. After the fortieth year, however, the deaths per hundred thousand show an increase in the year 1910 over all rates in the year 1900; furthermore, this increase is a progressive one, that is, the greater the age period the greater the relative and absolute increase. In the year 1900, between the ages of 40 and 50, there were 90.88 deaths per hundred thousand persons at that age, while in 1910 there were 101.36 deaths at the same period. In the period from 50 to 60 years, in 1900, there were 198.43 deaths per hundred thousand, and in 1910, 229.42 for the same period; while in the age period from 70 to 80, in 1900, there were 495.84 deaths per hundred thousand, and in 1910, 661.54. The greatest increase in mortality rates is seen in the age period from 80 to 90 years, which was 587.44 per hundred thousand of the population in 1900, and 811.87 per hundred thousand in 1910.

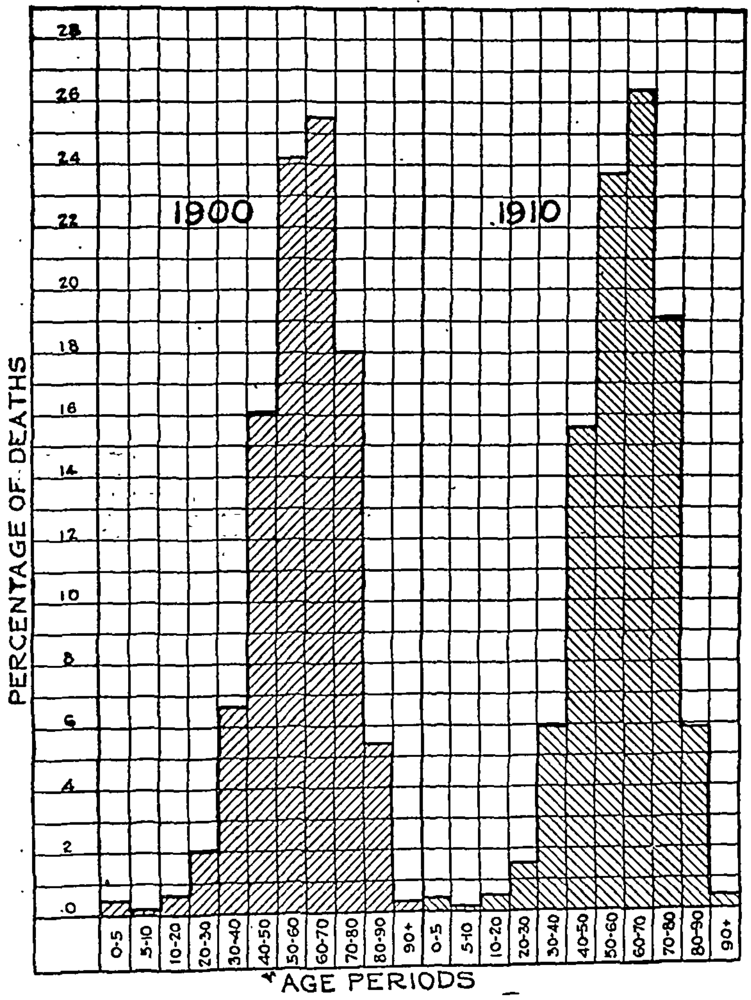

Chart 3.—Percentage of cancer deaths by age periods, 1900.

This is graphically illustrated in Charts 3 and 4. Chart 3 gives the percentages of deaths which occur in the various age periods. It will be noted (Chart 3) that the greatest percentage of cancer deaths in 1900 and 1910 occurred in the age period from 60 to 70 years and that the percentage of deaths declined rapidly to 90 years and over, but a true graphic picture of cancer mortality at various age periods is shown in Chart 4. Here it is seen that the deaths per hundred thousand of the population between 60 and 70 years is lower than in any of the age periods thereafter, even though that age period contributes the greatest number of cancer deaths. The most interesting point on this chart is the increase in the mortality in ten years as evidenced by the height of the column at various age periods in 1910 as compared with those of 1900.

SITE OF CANCER

Unfortunately the statistics concerning this most interesting phase of cancer mortality cannot be analyzed as they should be on account of the manner in which these causes of death are classified, but there are some points of general interest which are worth reviewing.

Table 5 gives the deaths per hundred thousand of the population from cancer according to the organs affected by year periods for ten years. The most frequent site of cancer, as evidenced by the mortality, is cancer of the stomach and liver, from which 31.2 persons out of every hundred thousand in the registration area died in the year 1913. The next in order of frequency is that of the female genital organs, the mortality for which was 12.2 per hundred thousand of the population. Cancer of the intestines, with a mortality of 10.5 is followed closely by cancer of the breast with a mortality of 7.3. In the decennial period 1904-1913, all forms of cancer show an increase. The most marked increase is seen in cancer of the intestines, 45.83 per cent., and cancer of the mouth is next in order with an increase of 40.90 per cent. Cancer of the breast with cancer of the stomach and liver increased 19.67 and 19.08 per cent., respectively. Cancer of the female genital organs increased 18.44 per cent., while cancer of the skin has shown little if any increase in the period. It is interesting to note here the percentage of increase of cancer which should be easy to diagnose, and that which is more difficult. From the standpoint of diagnosis, these cancers could be divided roughly into those which can be easily observed, and those of internal organs. The greatest percentage increase of cancer is that of cancer of the intestines, 45.83 per cent., which is nearly balanced by the increase of cancer of the mouth, 40.90 per cent., and, likewise, cancer

TABLE 3.—CANCER IN REGISTRATION STATES, 1900

Age Period	Deaths From Cancer Reg. States	Deaths per 100,000	Per Cent. of Total Cancer Deaths	Estimated Population, Registration States
0- 5	62	2.99	0.49	2,072,797
5-10	26	1.31	0.20	1,984,846
10-15 15-20	83	2.29	0.65	3,624,065
20-25 25-30	260	6.94	2.04	3,745,605
30-35 35-40	853	27.47	6.68	3,104,747
40-45 45-50	2,055	90.88	16.09	2,261,283
50-55 55-60	3,092	198.43	24.21	1,558,210
60-65 65-70	3,259	333.49	25.52	977,227
70-75 75-80	2,302	495.84	18.03	464,260
80-85 85-90	697	587.44	5.46	118,651
90-95 95 and over	46	464.27	0.36	9,908
Unknown	34	86.86	0.27	39,143
Total	12,769	63.97	100.00	19,960,742

of the stomach and liver has increased 19.08 per cent. and is balanced by an increase of 19.67 per cent. in cancer of the breast.

From the information obtained from the foregoing statistical tables we can come to but one conclusion, that is, that the cancer mortality is increasing. To be sure that the increase is real we must exclude the possibility of an increase in the number of reported deaths by better diagnosis, and changes in the population which would tend to add additional numbers to that portion in the cancer ages.

Undoubtedly new methods of diagnosis have greatly facilitated the detection of cancer, and if proper morbidity reports could be obtained the result of these methods would be reflected in the rates for incipient cancer, which would always include a fair percentage of obscure and borderline cases.

The matter of diagnosis of advanced cancer is, in most cases, a much simpler matter. The classical symptoms of advanced cancer are and have been the same for a number of years, and most physicians are conversant with them. In mortality statistics of cancer we are dealing with reports of cancer cases the symptoms of which are so evident as to be considered the primary cause of death, and the question of refined diagnostic methods and the inclusion of borderline cases cannot be a large factor in determining the rates. I submit that it is hardly probable that physicians of a decade ago were so deficient as not to be able to recognize advanced cancer.

TABLE 4.—CANCER IN REGISTRATION STATES, 1910

Age Period	Deaths From Cancer, Reg. States	Deaths per 100,000	Per Cent. of Total Cancer Deaths	Estimated Population
0- 5	159	3.27	0.44	4,867,909
5-10	64	1.44	0.18	4,438,038
10-15 15-20	197	2.28	0.54	8,652,398
20-25 25-30	562	6.25	1.55	8,992,169
30-35 35-40	2,152	29.29	5.95	7,347,865
40-45 45-50	5,642	101.36	15.59	5,566,408
50-55 55-60	8,589	229.42	23.73	3,743,780
60-65 65-70	9,576	429.01	26.46	2,232,102
70-75 75-80	6,926	661.54	19.14	1,046,950
80-85 85-90	2,139	811.87	5.91	263,467
90-95 95 and over	159	716.51	0.44	22,191
Unknown	28	36.17	0.08	77,416
Total	36,193	76.60	100.01	47,250,693

If the increase in mortality rates shown in the tables were dependent on changes in the composition of the population, we should have to consider sex and age distribution, the two possible changes which could bring about an increase in general cancer rates without an increase in the specific rates.

On reviewing the population figures for sex distribution in the registration states, I find comparatively little change in its composition. In 1900, 50.03 per cent. of the population was male and 49.97 female, and in the year 1910, 51.4 was male and 48.6 female. Since the incidence of cancer is considerably less in males than females, changes of this character in the population would, per se, tend to decrease rates. So far as the changes in sex distribution of the population are concerned we must eliminate them as factors in this rise in the cancer mortality shown in the preceding tables.

Knowing as we do that the bulk of cancer deaths occur after the fortieth year, any change which would add to the population after that year without a corresponding increase in that portion prior to the fortieth year would cause an increase in the general cancer mortality. A study of the population in the registra-

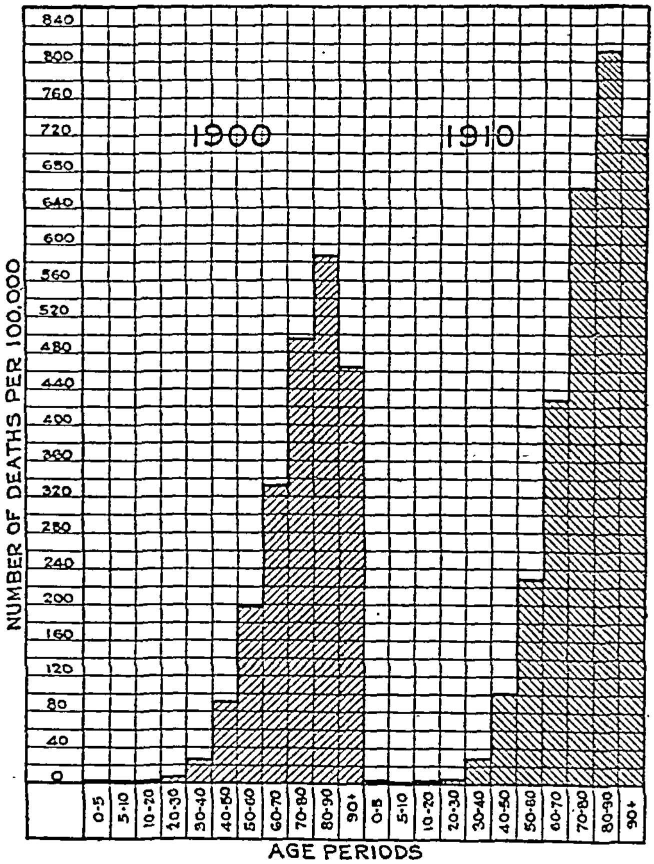

Chart 4.—Deaths per one hundred thousand of the population by age periods, 1900 to 1910.

TABLE 5.—CANCER IN REGISTRATION AREA; DEATHS PER ONE HUNDRED THOUSAND OF POPULATION FROM VARIOUS FORMS OF CANCER, 1904-1913

Location of Cancer	1904	1905	1906	1907	1908	1909	1910	1911	1912	1913
Mouth	2.2	2.3	2.2	2.3	2.5	2.8	2.9	2.9	3.0	3.1
Stomach and liver	26.2	26.3	26.1	27.0	27.9	29.3	30.6	29.3	30.6	31.2
Intestines	7.2	8.0	7.8	8.3	8.5	9.2	9.8	9.8	9.8	10.5
Female genital organs	10.3	10.7	9.7	10.2	11.2	11.2	11.4	11.3	11.7	12.2
Breast	6.1	5.9	5.8	6.0	6.5	7.0	6.9	7.2	7.3	7.3
Skin	2.3	2.4	2.3	2.6	2.7	2.9	2.7	2.7	2.9	2.7
Other or unspecified organs	15.9	15.9	15.2	14.6	12.3	11.3	11.9	11.0	11.6	11.9
All forms	70.2	71.4	69.1	70.9	71.5	73.8	76.2	74.3	77.0	78.9

tion states by age groups in the years 1900 and 1910 shows that the percentage of persons living in each age period did not vary by 1 per cent. in the ten years. The percentage of population included in the ages 0 to 40 years in 1900 was 72.80 and in 1910, 72.58, while the percentage of population included in the ages after 40 years in 1900 was 27.20, and in 1910, 27.42, differences so slight that they are negligible. More convincing is a comparison of the specific mortality rates. These rates are computed on the cancer deaths in certain groups of population, and no matter what changes are taking place in the composition of a population the only factor which could change the morality rates within these groups would be an actual increase or decrease in the number of deaths per one hundred thousand in any particular group. We have seen in Tables 3 and 4 there was a marked increase which is specific for each age period, and which must be in itself genuine.

If we cannot account for the increase in the cancer mortality by better diagnosis or by changes in the composition of the population I submit that for the past decade the cancer rates in the registration area show a true increase.

16 West Saratoga Street.

HOSPITAL INTERNSHIPS IN OPHTHALMOLOGY *

E. C. ELLETT, B.A., M.D.
MEMPHIS, TENN.

There are certain matters of interest to which your attention should be called. The first is in regard to the *comparative shortness of the program.* We were limited this year to fifteen papers, on account of the fact that the second day of the meeting is to be given up to exercises to commemorate the completion of the Panama Canal. In view of the important part that our profession has played in making possible the achievement of this great work, it is fitting that we turn aside for a moment from the main object of our coming together, and pay tribute to those workers whose discoveries and attainments have erected to their memories a "monument more lasting than brass."

We have further cause for a season of congratulation in that we are devoting ourselves to the celebration of a great commercial and engineering accomplishment, a work of peace, at a time when the older nations of the earth are wrapped in a terrible, destructive and desolating struggle; and in the enjoyment of the blessings of conditions that permit the unruffled pursuit of our usual work, we should not fail to both feel and express our sympathy for those, bound to us by the ties of a common task, whose lot is less fortunate, whose ways are less tranquil and whose labors are so rudely interrupted.

It has been the custom for many years for the section to invite a distinguished visitor from some other country to be a guest at the meeting; but after due consideration it was decided not to extend such an invitation this year. Disturbed conditions in Europe made it very doubtful if any of those whom we specially desired would have found it possible to come, and the shortness of the program already referred to made it seem advisable to give the time to our own members as a matter of choice and in justice to those who have brought the section to its present efficiency. Before the weight of these two conditions was fully realized, a sentiment was gaining ground to the effect that occasional, instead of regular, invitations to foreigners to participate in our meetings would be a more dignified attitude for us to adopt, and would at the same time make the recipient feel that he was the more complimented. In view of these facts, the officers of the section feel that they do not need to offer any apology for the omission of this feature.

The policy of the program has been, as in previous years, to encourage as much as possible those men who have not heretofore contributed to our proceedings; but you will find on the list some of those well-known names, without which a meeting of this section could hardly be successfully conducted, men to whom it is our pleasure to listen again and again. "Age cannot wither" them, "nor custom stale" their "infinite variety"; and may the day be far distant when our deliberations will lose the leaven of their presence.

Let me remind you, as my immediate predecessors have done, that the admirable features of the program are due to the energetic and well-directed efforts of our secretary, whose labors are the keystone of the arch, and without which our structure would fall to the ground. Nothing that I could say would be more than should be said in acknowledgment and appreciation of his more than efficient work, and those particulars wherein the program falls short of your expectations mark the occasions when an officious chairman or executive committee has interfered with his plans.

From appropriate committees a number of interesting subjects will be presented for your consideration, and among the most important is that of the Committee on Education in Ophthalmology. Their report is printed and will be distributed in time for it to be read by each of you before it is brought up for discussion and action. This committee, as you will see, met similar committees from the American Ophthalmological Society and the American Academy of Ophthalmology and Oto-Laryngology in Boston in October, and will present for your approval a plan whereby a board of nine would be appointed from these three organizations to pass on the qualifications of those desiring to appear as specialists in ophthalmology. While such a board will have no legal standing, its seal of approval can easily become the hall mark of genuine merit, and properly managed and supported by the organizations which create it, such a board could accomplish a great deal. Expressions from many quarters justify the expectation that this suggestion will be favorably received, and since this section has never been remiss in identifying itself with those things which stand for the advancement of ophthalmology, it can be expected to consider carefully their proposal, and approve it if it seems to promise what its sponsors believe it will do.

Another communication of much interest is that from the Committee on the Conservation of Vision. Although a child of this section, this committee was a youngster of such promise that it was weaned away from its real parent and adopted by the Council on Health and Public Instruction. We still retain an interest in its purposes and welfare, and are glad to know, from Dr. Allport's report, of the very excellent work which is being done. The need of some central organization with sufficient funds and adequate machinery for carrying on this work is being felt by all who have concerned themselves in it. Dr. Allport has given much time and labor to this matter, as any member of his committee can testify; but it is not good that the welfare of so great a cause should depend on the self-sacrificing efforts of any one man. It is hoped that all the interests looking to the conservation of vision will be federated and the work carried on from an adequate center.

---

* Chairman's address, read before the Section on Ophthalmology at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

Thanks to the activity and energy of the members of the committee, the Knapp fund continues to serve the usual purposes for which it was founded.

The fund furnishes the Knapp Medal for meritorious work presented to this section. The committee on award is of the opinion that no contribution made to the last meeting was sufficiently noteworthy to justify conferring the medal this year. Certainly the fund deserves the cordial support of all those interested in the progress of ophthalmology, and I especially request you all to support it. Subscriptions in sums of less than $10 will be gladly received, but they do not entitle the subscriber to the two volumes mentioned.

It is the custom for the chairman of this section to make some reference in his address to such point or points of interest to the Section on Ophthalmology as he thinks should have special attention or investigation. In accordance with that custom, it is my desire to invite your further consideration of certain aspects of the question which have been so to the fore in recent years, the preparation of the ophthalmologist for his his work. A phase of this subject which has not yet been touched on very fully is that of the available facilities for hospital work. Closely related to this are the plans which have been put into force in two of our leading state universities. One which was explained to you at length by my predecessor has had further trial during the past year at the University of Minnesota, and has given great satisfaction. Briefly, it consists in the employment of a number of men for a period of three years, at an increasing salary, who assist in the clinical work and in the instruction of the undergraduate and graduate students. These men are designated as "fellows," and the scheme contemplates the ultimate employment of six. The development of this plan was brought out in a paper before the Conference on Medical Education in Chicago in February. A somewhat similar plan is in vogue at the University of Michigan, where a man serves the department for three years as intern, assistant and instructor, respectively, one year each, at a salary which increases each year. The duties of the intern require no special elucidation. The second year is spent as assistant to the head of the department, with full charge of the operating room and morning treatments of all outpatients. In the third year he gives instruction in refraction, does refraction, and has charge of the laboratory in the mornings.

This scheme has suggested the idea that the very interesting work on the classification of hospitals by the Council on Medical Education, and the parallel work about to be undertaken by the American College of Surgeons, might be advantageously supplemented at this time by collecting information relative to the work offered by various special hospitals in this country in the shape of internships. A questionnaire was therefore formulated and sent to all the special hospitals listed in the American Medical Directory, and I wish to present to you the data gathered from a perusal of the replies. That this information is incomplete is true, but every one who has attempted a collective investigation will sympathize with the fruitless efforts that were made to secure responses from all the hospitals. Some institutions were inadvertently omitted, but the result is nevertheless of some worth.

The value of an internship is particularly great in postoperative work, but almost equally great in certain severe inflammatory and traumatic conditions. The whole question is summarized, and much more is suggested, by considering the case of those men who have had good "courses" in ophthalmology, with cadaver and clinical work, and who can perform a creditable operation for cataract, for instance, but who cannot tell the next day whether or not the eye is pursuing a normal and satisfactory postoperative course.

Answers were obtained by some means from twenty-five institutions. Many of these are eye, ear, nose and throat hospitals; but as far as possible to ascertain them, the facts set forth apply to the eye service alone. It was impossible to arrive, by any reasonable effort, at the facts concerning the special departments of general hospitals, but it must not be forgotten that in many of these an excellent service in ophthalmology can be obtained, and this is especially valuable where an outpatient department is also accessible to the interns. In such a case, the tour of duty for the intern should be simultaneous in the wards and outpatient department, since many of the patients are never house patients, and a service limited to the house would be inadequate. It would afford no opportunities for refraction, perimetry, muscle work, etc., and very limited ones for ophthalmoscopy.

Comments on the subject can be best made in a general way, because the information was not always exact. Previous general hospital experience is always desirable, but seldom required of an applicant. Since the supply of positions does not equal the demand, hospitals can fix rather high requirements, and certainly previous hospital experience, or a satisfactory equivalent in general practice, would be very desirable not only to the institution, but also to the future ophthalmologist, and should be a necessary condition for the applicant.

An outpatient department is maintained by all the hospitals answering this inquiry, but indefinite information was given in regard to interns' duties in that department. Unless the arrangement is to appoint the intern from the clinical assistants, or from externs, the interns should serve a definite tour of duty in the outpatient department, because the work in the house alone does not give sufficient experience with the various forms of functional examination and with the use of the ophthalmometer, ophthalmoscope, perimeter, and tropometer, with which one must be familiar. Refraction, which constitutes such a large and important part of the daily work of the ophthalmologist, can be learned only by practice, and the opportunity for this is found only among the outpatients. The same can be said of many of the minor ailments and milder inflammatory diseases, which constitute a much larger part of one's work, especially in the beginning, than serious maladies and capital operations.

In reading over the replies to the circular letter, one is impressed with the fact that a hospital intern is no longer at school. Little is demanded of him beyond a certain amount of routine work. He does some history taking, which varies greatly in quantity and quality in different places, and renders a certain assistance in the care of patients, operating room duties, etc. He has abundant opportunities, but there is no one whose duty it is to see that he profits by them. In the larger institutions with a graded house staff this is not the case, and the junior is not only given a certain amount of instruction by the senior, but is required to perform certain duties. This is very desirable, and in proportion as this system does not exist, the present plan seems to fall short of accomplishing the best results. As was pointed out in the report of the Committee on Hospital Efficiency of the Philadelphia County Medical Society, one of the functions of a hospital is the education of doctors and nurses, and some plan could be profitably adopted whereby the intern could receive more or less systematic instruction, and be actively supervised in his work, which would greatly increase that particular hospital's efficiency as an educator. When we consider that the average intern enters on his duties in a special hospital in the most profound ignorance of the rudiments of his work, the advisability of such a plan would seem to be apparent. Various ways suggest themselves for solving this need. In institutions in which systematic instruction is given, he should be required to attend such instruction, that is, lectures, in the first part of his term. Otherwise the matter could be placed in the hands of a senior intern or house surgeon; or, if only one intern is employed, in the hands of an executive officer or committee or some one specially charged with the work. A little systematic instruction at the beginning will clarify many otherwise confusing subjects, and this instruction can take the form of quizzes, lectures or merely the outlining of a course of study, with such conversations or other interrogations from time to time as will enable the intern to demonstrate that he is preparing himself to take advantage of his opportuni- preparing to take advantage of his opportunities. eases and surgical work will be presented to him sufficiently forcibly; but some special means should be taken to see that he avails himself of the opportunities that are offered to study refraction, ophthalmoscopy and ocular pathology. An intern, like a student, is rarely able to proportion his work wisely, and a little guidance from some one more experienced would enable him to use his time and opportunities to the best advantage. In brief, our present plan gives a man abundant opportunities, but fails in that it does not insure his taking advantage of them.

Incidentally, this inquiry has revealed some interesting facts in regard to the special hospitals in other particulars. You are all aware that the American Medical Association is now conducting an investigation and classification of hospitals, and out of this work will come much good along the line of which I have especially spoken, as well as in other matters pertaining to hospital efficiency. With such plans as those in use at the universities of Minnesota and Michigan, and the systematic course in ophthalmology given by the University of Colorado, and the graduate courses now being formulated by Harvard University, and the close relation which obtains and which is being further developed between the department of ophthalmology and the department of research medicine at the University of Pennsylvania, both precept and example are at the disposal of those who are charged with these problems of medical education.

CHRONIC NEPHRITIS

ANALYSIS OF 250 CASES IN PRIVATE PRACTICE*

W. JARVIS BARLOW, M.D.
AND
R. L. CUNNINGHAM, M.D.
LOS ANGELES

These 250 cases have been tabulated from patients in our private practice occurring over a period of eighteen years. They are considered entirely from the clinical standpoint, and as they represent, in the main, office cases or ambulant patients, they must be regarded as representing Bright's disease of the milder or earlier type. There is no intention here to enter on the intricate mass of renal pathology, nor have we investigated or tried the several functional kidney tests, which lie beyond the province of this paper; but it is intended to call attention to several groups of nephritic cases observed and treated in Southern California. In making the diagnosis, other factors than the examination of the urine have been considered. It is certain that many patients who show traces of albumin and a few casts do not suffer from nephritis, while true renal disease may occur without albuminuria; but we do recognize that certain persistent findings in the urine, accompanied by changes elsewhere with definite symptoms, are manifestations of a primary or secondary disturbance of the renal function which, when early recognized and given proper treatment, is easily controlled and may become quiescent or arrested.

For the better study of these cases for clinical purposes, an arbitrary classification into four groups has been made (Table 1).

TABLE 1.—CLINICAL GROUPS OF NEPHRITIS CASES

	No.
1. Primary	75
2. Cardiovascular	82
3. Miscellaneous association	24
4. Secondary to tuberculosis	69
Total	250

With few exceptions, our cases of true nephritis fall clinically into what is called the chronic interstitial type, in which class they will be discussed. The exceptions include a few that belong to the chronic parenchymatous type and are numbered among those in Group 2, who died; one patient in Group 1 died—acute hemorrhagic. A few others, at first acute or parenchymatous, improved, and naturally fell into the interstitial variety which, we believe, includes most of the degenerative changes that take place in the kidney, whether primary or secondary, as well as the contracted or sclerotic kidney.

EXPLANATION OF CLINICAL GROUPS

The cases are placed into these groups with reference to their apparent etiology.

Group 1 embraces those which, from their history, followed acute infectious diseases and alcohol, as shown in Table 2.

Group 2 embraces those which accompanied, preceded or followed chronic endocarditis or arteriosclerosis, with or without a history of definite earlier infection.

---

* Read before the Section on Practice of Medicine at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

Group 3 embraces those which occurred in the course of chronic diseases, infectious or otherwise, and which could not naturally fall into the other groups.

Group 4 embraces those which occurred in the course of pulmonary tuberculosis.

In Table 3 are given the age at onset of disease, sex, and previous duration of disease for each of these groups. In Chart 1 the early symptoms are shown. The occupation is given in Table 4.

Only the fourth or tuberculous group is not carried out in detail, as the course, treatment and results were dependent on the pulmonary trouble, and did not seem pertinent to the paper. Where there was a true nephritis, the pulmonary symptoms were aggravated; therefore, on the whole, the discussion limits itself to the first three groups.

More than 25 years	1	2	0	1	4

It would seem that the true nephritis, or destruction of renal tissue, belongs to those cases of Group 2—cardiovascular. Whether or not those in the other three groups can rightly be classed as true nephritis, until real vascular changes elsewhere have taken place, is an open question. Certainly, in following several patients in the first, third and fourth groups, we have found that their trouble has disappeared and the urinary findings have become normal after periods ranging from several months to two years, and we do not believe that nephritis is so cured. It has been said that there is an early, curable stage of nephritis, with slight renal changes, in which the kidney again assumes its normal function; but it seems, from a clinical point of view, more probable that these cases are merely a result of toxemia and do not produce any real permanent change in the kidney tissue. Examples of this type are eighteen cases (thirteen in Group 1 and five in Group 3) in which the urinary findings became normal. The largest number began after chronic constipation and gastro-intestinal disturbances, three after severe tonsillitis, two after acute alcoholism, one after pleurisy with effusion, and one patient has had albumin with granular casts in his urine for thirty-five years, discovered through life insurance examination, and, at present, clinically well, aged 51. In none of these did the heart appear enlarged or the second aortic accentuated. Other cases of similar nature, but of shorter duration, not here included, have occurred in our practice, but with sufficient frequency to emphasize their clinical occurrence. In Group 4, the tuberculous group, it has been a frequent observation that, as the pulmonary trouble improves, the albumin and casts have disappeared, along with increased elimination of urea. The continued taking of abundant or of excessive protein many result in similar findings, a fact which has been noted often in tuberculous patients. One of this type, aged 37, in Group 4, has been under observation six years, and during this period he suffered for two years, off and on, from repeated attacks of headache; at the same time albumin and casts appeared in his urine. It was found that each time these attacks occurred he had returned to an increased or forced protein diet. For the past two years the excessive proteins have been cut off, with the result that symptoms have disappeared and the urine remains normal, so that, excepting the infectious type, included in all four groups (because even the fourth or tuberculous group shows severe infection in the last stages), the disease tabulated can well be caused by toxemia, which may soon disappear, or continue to manifest itself

until other organs as well as the kidneys become involved, vascular changes take place and true nephritis results. When true nephritis is present, the best outcome possible is an arrest of the disease, and that the patient be clinically well for years.

AGE AND RESIDENCE AT ONSET

The analysis of the several groups shows such results as one would expect. Primary has the largest number in the fourth and fifth decades; cardiovascular in the fifth, sixth and seventh decades; tuberculosis in the third and fourth. In all four groups, the previous duration of the illness shows that the largest number suffered from two to five years. The occupations give little information except that they are among indoor workers, and the larger number had previous mental or physical overstrain.

The residences of these patients and the location at the onset of the disease have been carefully studied in each case. Neither had any special bearing, one way or the other. A total of ninety-eight patients resided in the Pacific Coast States at the onset of the disease; seventy-two in the Central States, seventy in the Atlantic States, and ten developed their trouble in foreign countries.

EARLIEST SYMPTOMS

Among the earliest symptoms in the primary group, the most frequent, in their order, were weakness, cough and asthmatic symptoms, digestive disturbances, headache, muscular pain, and nervousness and restlessness. Each of these is easily accounted for, and it would seem that the chest symptoms are due to the development of chronic bronchitis and emphysema, so often found secondary to nephritis. Contrasting this with the same cases during the course of treatment, we find the digestive disturbance comes first in frequency, nervousness and restlessness second, and there is a marked diminution in complaint of weakness, as well as headache and asthmatic symptoms.

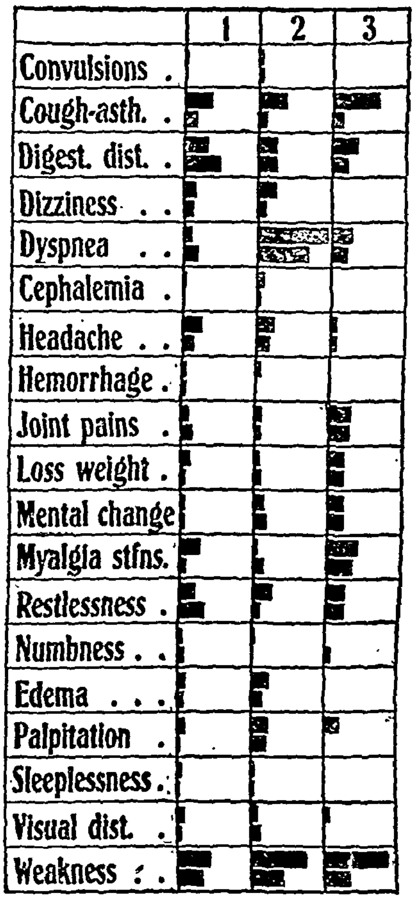

Chart 1.—Early persistent symptoms.

In Group 2, the chief early symptoms, in order of their frequency, are dyspnea, weakness, cough, vertigo, digestive disturbance and edema. During the course of the treatment of patients of this group, dyspnea, which was the most frequent early symptom, disappeared in eleven of the cases, while the weakness, cough and edema disappeared in about 50 per cent.

In Group 3, the earliest symptoms in frequency were weakness, cough, digestive disturbance, dyspnea and joint pains. During the time of treatment, the cough and dyspnea lessened, while the joint pains remained in evidence. The joint pains in this group are explained by the four cases of chronic infectious arthritis, and marked pyorrhea alveolaris, in which the *Streptococcus viridans* was grown from the roots of removed teeth and vaccine given. It is interesting to note that the cough or asthmatic symptoms in each group diminish to a minimum under treatment, and a marked improvement occurs in the weakness and digestive disturbance.

The marked symptoms of dyspnea in Group 2 can be explained by the cardiovascular complications. Here are found the cases with the high blood pressure and arteriosclerosis. Arteriosclerosis, other than that due to syphilis, seems not well understood, but it appears to be the result of longstanding hypertension, which, with cardiac hypertrophy, is generally recognized as a compensatory factor to nephritis, aiding the kidney in maintaining its function.

Of course, arteriosclerosis may cause nephritis, and it appears that each may be the cause of the other. In the second group, the cardiac hypertrophy alone occurred in forty-four and the second aortic sound was accentuated in forty-seven cases out of the sixty-five. The Wassermann test was made and found negative in nine cases. Syphilis occurred in five cases, with a positive Wassermann reaction.

The percentage of retinal changes found was less than is usually reported. It was surprising in looking over the cases to find how little complaint of disturbed vision was made, and often no retinal change was found in the early or less severe cases. Marked retinal changes were shown in eight cases by neuroretinitis (arteriosclerotica) and in seven by hemorrhage into the retina; they occurred among the fatal cases. These always indicate a bad prognosis, of from six months to one year as the average duration of life. In Group 2, hemiplegia occurred in five cases, varying in severity from partial paralysis to complete loss of power.

OBJECTIVE FINDINGS

While the greater number of these cases came under observation before the present functional tests for the renal activity were available, it may still be of interest to note briefly the facts represented by those commoner methods of examination which have been longer in use. The higher readings of specific gravity were found in Groups 1 and 3. The average of all readings in Group 3 was lower than in any of the other groups, and depended (of course) chiefly on the total amount of urine, which was usually large. Readings of less than 1.005 have been frequent, and have occurred in each group, the lowest being 1.002, in Group 1.

Albumin was present at one time or another in all of the urines examined, only a few specimens, however, showing more than a slight cloud, and many showing but extremely faint traces. Many cases had intervals of freedom from albuminuria, but in all cases the albumin reappeared with exacerbation of symptoms.

Cylindruria, too, has been constant, the granular casts being by far the most frequently found, with hyaline coming next; a fair number had waxy casts at times, while only three had epithelial casts. We have not seen any special significance in the type of casts observed.

The urea has been followed as closely as possible, and the results of our examinations tabulated. Nothing of special note is shown. Roughly, the amount of urea excreted in the urine has varied with the diet. In some instances, the low output of urea was associated with exacerbations of the disease, the severe symptoms and the lower urea being both signs of deficient renal activity. In these cases we have seldom seen a high urea except when the patient was doing well clinically. In several instances we have seen a decreased urea output precede a clinical retrogression, and we have often seen an increased urea output followed by clinical improvement. We therefore do believe that it is a help to determine the urea of the urine when the diet is known and conditions can be controlled. We acknowledge, however, that we have found these observations to be of help only when supported by clinical evidence.

Our systolic blood pressure readings cover most of our cases, and for a great many of them a large number of readings were taken. As we would have expected, our highest readings were found in cases of the cardiovascular group, the highest being 270 mm. Hg, average 169 mm. Hg. Here, too, was the highest average blood pressure. Next comes the primary group with an average of 141 mm. Hg, then the miscellaneous group with an average of 127. In the tuberculous group we found lower readings than elsewhere, as a rule. The lowest reading of all recorded was 80 mm. Hg, in a case of Group 3, *Streptococcus viridans* infection with arthritis, which had also the clinical picture of toxic nephritis. This is hardly in accord with the statement of Struempell that all renal disturbances are associated with elevated blood pressure. Certainly, in these cases, the blood pressure was more markedly elevated in those nephritics who had also well-developed arteriosclerosis, especially with atheroma, than in those which we have looked on as primarily renal disturbance.

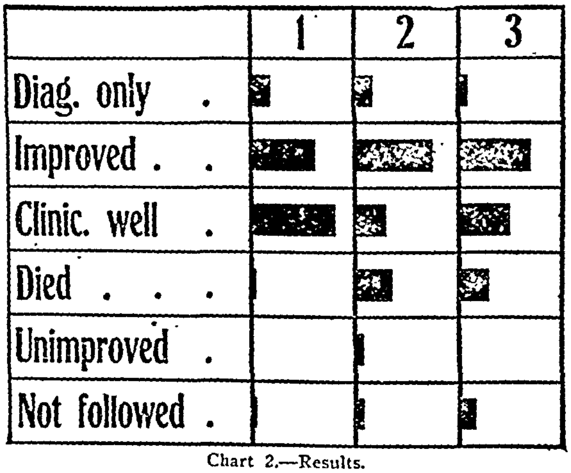

Chart 2.—Results.

TREATMENT

Treatment will be considered under the following topics: (1) climate; (2) diet; (3) rest and exercise; (4) hydrotherapy, and (5) medicinal.

Climate.—Next to pulmonary tuberculosis, chronic nephritis and convalescence from acute kidney trouble are most benefited by climatic treatment. With that possible exception, no other disease is so favorably influenced by climatic conditions. Surely we are convinced that the conditions in Southern California which our patients have enjoyed have added most to their comfort, relieved their symptoms, and helped to produce good elimination and given longer periods of apparent help. The results, to come later, will speak for themselves. These patients do well near the coast in Southern California, quite as well as in the interior part, because humidity is not so much a factor here as in some other chronic diseases. The warm, equable climate, with little wind and low elevation, is a most important factor. It might be stated, however, that though humidity seems of less importance, these nephritics are in better health during our dry season—from July to January—than during the moist season of the other six months, especially those who have joint, muscular or gouty symptoms.

One of us (W. J. B.)[1] has stated in a former article that it is important that residence in such a climate should extend over a period of one or two years, under medical supervision; but in studying cases for longer periods of time, the conviction is forced upon us that many may remain clinically well in a suitable climate, over an indefinite period of years. There are no apologies to make for the outdoor life given this class of patients in Southern California, anywhere from the coast to 50 miles inland, along the foothill region and outlying valleys which offer low altitude and equable atmospheric conditions.

Diet.—Diet has been an important factor in all cases; but in any of the forms of treatment, individualization has been studied and not alone the disease. The objective findings, such as urine, blood pressure, etc., are considered less than the individual requirements. Some have contended that there is no real difference between the red and white meats for nephritic patients, but experience has shown us that it is best to cut out the red meats from the diet, but not to cut off too much of the protein. Two or three eggs are allowed daily, with plenty of cream, butter, cereals, buttermilk, etc. Fortunately, our patients can have fresh vegetables the year round. Highly spiced and all fried foods, strong cheese and alcohol are to be avoided. It is best to have patients take their water between meals, giving them from six to eight glasses in the twenty-four hours, one-third of which should be some alkaline water. One should guard against the excessive use of water.

---

[1] Barlow, W. J.: Hare's Modern Treatment, 1910, i, 158.

Rest and Exercise.—This is ordered according to the patient, each one getting two hours of rest on his back in the afternoon. The blood pressure is certainly lowered by rest and light diet. Exercise, of course, is prescribed according to the case.

Hydrotherapy.—This is one of the most important divisions of treatment. Hot baths two or three times a week, in the form of vapor, electric or Turkish baths, followed by massage and rest, give free elimination by the skin and establish a right habit for future elimination, and seem to have a beneficial effect on the bowels. Several patients have had electric cabinets installed in their homes, so that treatment can be carried out regularly for years; where such is not possible, hot baths followed by wrapping in blankets have sufficed. Bowels have been kept active by cooked fruit, fresh vegetables, the coarser cereals and liquid petrolatum.

Medicinal.—Drugs have been used infrequently except where the heart muscle has needed help, or when the amount of urine passed was low. Digitalis for failing compensation, whether the blood pressure is high or low, acts well, and certainly, in these cases, high blood pressure is no counterindication for its use. Caffein, spartein and strychnin have seemed also very helpful.

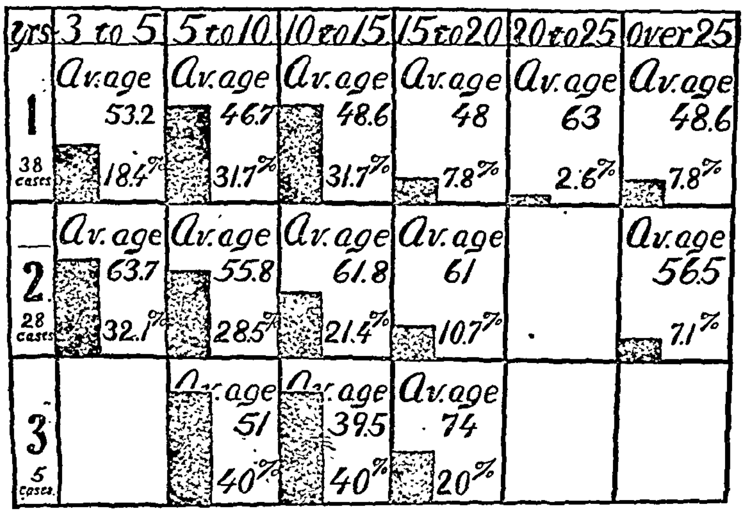

Chart 3.—Duration of disease and average age of seventy-one patients now under observation.

RESULTS

The results are studied and tabulated (Chart 2) in the three groups only. The fourth group, occurring secondary to pulmonary tuberculosis, has been omitted, as really belonging to a separate paper, and because the symptoms of nephritis were chiefly dependent on the primary disease. It was found that already too much time had to be given to segregating, classifying and studying results of the three more important groups. Therefore, omitting the sixty-nine cases in Group 4, there remain 181 to be reported on (Tables 6 and 7).

TABLE 6.—DURATION OF OBSERVATION IN ONE HUNDRED AND EIGHTY-ONE CASES

Duration of Observation	No.
Seen once only for diagnosis	17
Not followed after two months	20
From two to six months	28

From one to two years	28
From two to five years	41
From five to ten years	14
From ten to fifteen years	11
Sixteen years	1
Eighteen years	1
Groups 1, 2 and 3	181
Group 4	69
Total	250

It is to be remembered that these results are given up to the time the patient was last treated, and many have not been followed up to the present time.

The statement that so many of these patients have been called clinically well may be attacked, and the answer is that from the clinical standpoint, the patients when last seen had been free from all suggestive symptoms and felt well.

Of the 181 cases tabulated, there are forty-seven, or 26 per cent., still under observation, after three or more years of treatment, grouped as in Table 8.

TABLE 7.—STATUS IN ONE HUNDRED AND EIGHTY-ONE CASES

Condition	Groups 1	2	3	No.
Not followed	1	3	2	6
Unimproved	..	3	..	3
Improved	28	37	10	75
Clinically well	37	14	7	58
Dead	1	17	4	22
Diagnosis only	8	8	1	17
				181
Group 4				69
Total				250

Table 9 shows the duration of time of the whole illness, or the time during the observation of the case plus the history of kidney trouble, in sixty-one cases. Only such cases are taken from our total number as have had trouble over three years.

CONCLUSIONS

1. The prognosis of chronic interstitial nephritis is favorable when patients can be placed under proper conditions.

2. Many cases of so-called interstitial nephritis are not true disease of the kidneys, and often these patients have no return of the abnormal urinary secretion.

3. Patients with chronic interstitial nephritis, with good vascular and cardiac compensation, may live comfortably, and indeed, enjoy good health, for twenty-five or thirty years, and probably longer.

TABLE 8.—GROUPING OF FORTY-SEVEN PATIENTS STILL UNDER OBSERVATION

Observation	Groups 1	2	3	No.
From 3 to 5 years	11	9	4	24
From 5 to 10 years	5	5	1	11
From 10 to 15 years	6	3	1	10
Sixteen years	..	1	..	1
Eighteen years	1	..	..	1

TABLE 9.—DURATION IN SIXTY-ONE CASES

Duration	No.
Under 10 years	25
From 10 to 15 years	25
From 15 to 25 years	7
From 25 to 30 years	3
Thirty-five years	1

4. Such patients may reach an arrest of the disease, they may be clinically well, and can be classified as apparently cured, quite as surely as in other chronic diseases.[2]

---

[2] Since the completion of this paper, report has come of the death of one more patient in Group 2.

ABSTRACT OF DISCUSSION

Dr. Alexander Lambert, New York: There are many conditions grouped under nephritis which do not rightly belong there. Dr. Barlow has shown how markedly different are the conditions and course of the affections due to acute infections or injuries of the kidney and those due to chronic conditions which show arteriosclerosis. The charts show in asthma, for instance, that the dyspnea of acute nephritis is a very different condition from the same symptom in the cardiovascular affections of the kidney. You can secure more improvement in the acute than in the chronic cases. It is curious that if a man lives for from five to fifteen years sick, after standing that strain he will stand a better chance of living for twenty-five years. In the acute affections, if the patient survives he is in a much better condition for recovery than if the blood vessels are injured. The charts are beautiful in a pictorial way. The kidneys are virtually a pair of filters. If they are handed something that injures them, metabolic cobblestones when they are fit to handle only metabolic sand, they cannot handle them and the kidney is injured. One must remember the more specialized the cells the less do they possess general defenses; they are more liable to be injured because of their special character. The great number of the mixed class or the class of vascular sclerotics are the ones that have so much to do with the metabolic changes occurring from the action of the thyroids and the liver. We do not know the cause of the uremic poison and we do not know where the metabolic injury lies, but it is there even when the kidneys are doing their work. There is something back of it all. You may see it in the dry skin, the chippy nails; you may call it gout if you please; it is the same as any hypothyroidism, which may improve when the patient is fed on thyroid. It is a question as to what you can do for these patients. Dr. Barlow has brought out very clearly the fact that their environment influences these patients more than it does the normal individual. No patient is more rapidly injured by little things than nephritics. They do well at equable temperatures where extremes do not occur. They do well if they are willing to exercise self-control both in food and drink, and they do ill if they do the reverse. The ones that have the cardiac troubles and the vascular troubles are the ones doubly struggling against the two injuries, as these charts show. A study of these charts is well worth the time, because they show very clearly the clinical symptoms and the clinical conditions brought before us. We have not solved the problem as to what is behind nephritis. These charts show the prognosis, when it is good and when it is bad.

Dr. Philip King Brown, San Francisco: At the Southern Pacific Hospital in San Francisco a large number of young males enter the hospital for all sorts of diseases and injuries. In a study of the records of the hospital for the last two years, covering six thousand admissions, Dr. Cummins and I have tabulated the cases of albuminuria with casts, separating out as cases of chronic interstitial nephritis those with blood pressure much above normal. We have tried to find out from the comparative study of the etiology and functional kidney tests of the patients who had high blood pressure and could be classed as chronic interstitial nephritis, and those with low blood pressure, what the relation was between these classes among workingmen and the prognosis in each class. Our results differ from Dr. Barlow's, which only emphasizes the point he has made, that if you can surround these patients with the proper environment, mild climate and proper food, with light or no work, life can be much prolonged. In our cases, we find that no working man has lived longer than five years after the diagnosis has been made. This striking difference seems to me to be entirely due to the fact that we have to deal with a lower intelligence, limited means, and it requires greater effort for these individuals to live properly. It has been the routine of the hospital of late to study the Wassermann reaction in every case, and we find the cases of chronic interstitial nephritis in which syphilis is an etiologic factor are very much less amenable to any kind of treatment. Contrary to the accepted law, we administer to such patients considerable quantities of salvarsan, together with other antisyphilitic remedies, without influencing for the better the course of the disease. In established cases of arteriosclerosis, in which the pressure is low, the appearance of an acute infection has impressed us as influencing decidedly the development in the kidney of further interstitial changes. Some of our patients that have entered the hospital with infected wounds, for example, have undergone striking interstitial changes, the blood pressure increasing from normal or less to away over 200. We do not believe that a man with interstitial nephritis can continue his work safely. We have studied our cases with reference to type of labor. Only with clerks and others whose occupation is sedentary can the length of life be prolonged to any extent. Most of us have to do with individuals whose incomes are limited and dependent on their work, and while I believe strongly that bad prognoses are not necessarily to be made, I do feel that for the working man the best therapy is a change of occupation to something quite mild, sedentary if possible.

Dr. Joseph S. Cipes, Albuquerque, N. M.: Strong as this paper is, I notice that the cases in the fourth series receive little attention. This, I believe, is due to the fact that when we have a patient suffering with pulmonary tuberculosis and we notice a slight edema or a few symptoms of nephritis, we think there is no use trying to do anything for him. A good many cases that are prognosticated in that way, turn out just contrary to the prognosis given by the physician. The bad prognosis given is due largely to negligence or carelessness in making the diagnosis. When nephritis complicates tuberculosis, it is our duty to find out the exact type of the condition. Chronic parenchymatous nephritis, when found complicating pulmonary tuberculosis, usually results fatally. Chronic interstitial nephritis, however, when it follows tuberculosis, is often not fatal. The patient may live a number of years after he has developed an interstitial nephritis. It is a very easy matter to differentiate the two. The differentiation can easily be made by the administration of methylene blue. When administered to a patient in a case of chronic parenchymatous nephritis, the secretion of the methylene blue is usually retarded, whereas in interstitial nephritis it is excreted just as if the patient had no disease of the kidney.

Dr. W. Jarvis Barlow, Los Angeles: I was very glad Dr. Lambert brought out the point of the duration of the disease. If the patients stand the trouble from two to five years or more, they may go on indefinitely under the right supervision and the right care of themselves. I think this is brought out also in what Dr. Philip King Brown said of his statistics of working men. He tells us how very different are their results from those presented here, and to be frank with you I thought our results would be somewhat the same. We were very much surprised to find that our results tabulated as they have. It may be explained by the fact that the cases belong largely to the leisure class, with the opportunity to rest and take care of themselves. They were not among the working class. Perhaps 75 to 80 per cent. were able to settle down and take proper care of themselves. And why should not the results in such cases be better than in the case of the working man?

Progress.—We are gradually acquiring through the natural development of the processes of medical growth a system for the scientific management of disease. The past is full of stimulating traditions; the present, filled with the grains of precious wisdom that have been extracted from the mountains of theory and conjecture; and we accept the truth that in the future what we now worship will be swept away in the melting-pot of scientific ardor. But in admitting our limitations, we affirm with greater confidence our optimisms. It is only when harassed and perplexed that men learn; "strength grows out of weakness."—Everett A. Bates, M.D., *Boston Med. and Surg. Jour.*

PRENATAL CARE

DEDUCTIONS FROM THE STUDY OF THREE THOUSAND FOUR HUNDRED AND SIXTEEN CASES *

MARY LEE EDWARD, B.A., M.B.
Assistant Attending Obstetrician at the Infirmary for Women and Children
NEW YORK

The infant mortality statistics in the New York Infirmary for Women and Children seem worth publishing at this time when prenatal care is receiving so much attention, partly because we have had a regular prenatal clinic for over twenty years, and also because the results show a gradual general improvement, following increased care and improved facilities in the clinic.

The accompanying table shows statistics of the stillbirths and the deaths, within two weeks, for the last eight years since the rebuilding of the hospital.

MORTALITY STATISTICS FOR THE PAST EIGHT YEARS

Year	Infants Born	Still Births	Per Cent. of Births	Deaths First 14 Days	Per Cent. of Those Born Alive
1907	146	5	3.4	9	6.38
1908	280	12	4.2	10	3.7
1909	357	19	5.3	9	2.6
1910	374	15	4	9	2.5
1911	523	26	4.9	10	2
1912	552	14	2.5	13	2.4
1913	587	20	3.4	11	1.9
1914	597	15	2.5	18	3
	3,416	126	3.6	89	2.7

Total mortality, 215, or 6.3 per cent.

Our total percentage of stillbirths is 3.6 as compared with 4.29 per cent. in Sloane Hospital and 5.22 per cent. in the Universitäts Frauenklinik in Munich (quoted by Holt and Babbitt[1]). The percentage of deaths in the first fourteen days is 2.7 as compared with the 3.1 per cent. in Sloane Hospital. The total mortality of 6.3 per cent. is perhaps not so much of an improvement over Williams' 7 per cent.[2] as our approach to his description of an ideal clinic should warrant. It is, however, a step in the right direction, and the fact that our mortality tends to decrease is encouraging.

The 215 cases were divided as follows:

Abortions (under 37.5 cm. or 1,500 gm.)	32
Premature (37.5 to 46 cm. or 1,500 to 2,500 gm.)	44
Full term (46 cm. or 2,500 gm. or over)	125
Development unrecorded	14

Exclusive of the thirty-two abortions, in thirty-four cases no heart was heard on admission and, of these, twenty-one fetuses were macerated. Thirty-nine of those born alive, or 1.1 per cent., died the first day; 2.1 per cent. (seventy-three) during the first seven days, and 2.7 per cent. during the first two weeks. The causes of early mortality, with the exception of one case in which the necropsy report gave meningitis, did not differ from the cause of stillbirth.

The causes of total mortality are:

Labor (forceps 27; cranitomy 3; rigid cervix 2; breech 13, with 2 impacted; long labor 7; shoulder 1; early induction 2; fibroid of cervix 1; polyp of cervix 1; flat pelvis with version 1; placenta praevia 14; prolapsed cord 12, with 2 pulseless; cord about neck 6; concealed or accidental hemorrhage 3)	93, or	43 per cent.
Syphilis	14, or	6.5 per cent.
Undetermined	28, or	13 per cent.
Deformity	19, or	8.8 per cent.
Prematurity and inanition	20, or	9.3 per cent.
Toxemia	7	
Asphyxia	6	
Nephritis	5	
Atalectasis	3	
Cerebral hemorrhage	4	
Endocarditis in mother	3	
From other causes	13	

The other causes were ten in number and were acute hydramnios, with labor induced, 2 twins) pertussis in mother 2, typhoid in mother 1, general infection 1, intra-uterine infection 2, intraventricular hemorrhage 1, meningitis 1, perisplenitis 1, hemorrhages into brain, lungs, liver, etc., 1, edema of the brain 1.

LABOR AS FACTOR

The largest of these groups deserves special mention. The percentage caused by labor, while not unusually large, shows possibilities of reduction. Unfortunately, most of these possibilities occur at the actual time of delivery and not in prenatal care. Here the question of personnel is a large factor, for we have a teaching hospital with a changing house staff. In ten of the cases of prolapsed cord, for instance, judgment and dexterity might have done much to save the fetus. In eleven of the cases of breech extraction, a slight delay or a false movement may have been to blame. Placenta praevia causes a comparatively large infant mortality, as, through fear of infection, we do not undertake cesarean section. The deaths incident to forceps deliveries might possibly have been lowered in private practice, but the figures here given include cases of dystocia from the cervix as well as from the bony pelvis. In some of these, delay may have been a factor through nonobservance of the earliest change in tone or rate of the fetal heart; in others, permission for cesarean section or induction was withheld; but the large majority were borderline cases—either flat pelves with a true conjugate of 8.5 cm. or justominor pelves in which the disproportion did not seem to warrant cesarean section. The question is often one for close consideration.

SYPHILIS

Our percentage from syphilis is comparatively small, 6.5 as compared to Williams' 26.4 per cent. The latter percentage is, however, due to the fact that of the patients composing the Baltimore clinic almost half are colored. Moreover, some patients in our undetermined class of 13 per cent. were probably syphilitic. In any case, making all allowances, it seems positive that treatment has lowered the mortality.

Cases of deformity, monsters, etc., except for the treatment of a possible underlying syphilis, offer no hope of reduction with our present knowledge. Unfortunately, even when syphilis is treated, the time is often too late to correct any embryonic defect.

[2] Williams, J. Whitridge: The Limitations and Possibilities of Prenatal Care Based on the Study of 705 Fetal Deaths Occurring in 10,000 Consecutive Admissions to the Obstetrical Department of the Johns Hopkins Hospital, The Journal A. M. A., Jan. 9, 1915, p. 95.

The cases of prematurity and inanition undoubtedly depend on poor home surroundings of the mother. Five of the twenty cases were twin births and naturally the infants had a poorer chance to survive, but the large factor is probably sociologic and through the clinic the social service is able to help in these cases.

CLINICAL MANAGEMENT

The prenatal clinic, as at present managed, is under the direct supervision of the attending obstetrician. The assistant in the department and the intern follow the cases. Complications, such as tuberculosis, endocarditis, hyperthyroidism, abscess, etc., are looked after in conjunction with the doctors of the other departments of the dispensary, as deemed advisable. We have no prenatal visiting nurses, but the social service cares for patients who seem in need. Medical instructions are given by the doctors.

Patients register at seven months, sometimes at six months; they make bimonthly visits till the end of the eighth month and weekly visits during the last month. Patients not reporting for a period of a month are debarred. The patient's history is taken at the first visit, especially as to history of past diseases, former labors or abortions, and health during present pregnancy. The physical examination, unless otherwise indicated, is obstetric only, consisting of external and internal pelvic measurements and abdominal palpation, mensuration and auscultation. In making the internal examination, the condition of the cervix and perineum is noted and any erosion of the former is treated.

Syphilis is conceded to be the largest single factor in prenatal death, and while we are not able to treat patients in the early months, every registered patient presenting any symptoms or giving any history suspicious of syphilis has a Wassermann examination and if complement fixation be positive, has a course of salvarsan. The history we most commonly get in positive cases is one of abortion, stillbirths, or children dying in early life—often of "infant's consumption."

Furthermore, accurate or at least careful pelvic measurements help to reduce the cases of dystocia, due to the bony pelvis, to a minimum, for while no one's judgment is infallible, early observation allows more intelligent treatment.

Routine urinalyses have enabled us to eliminate toxemia almost entirely, some of the seven cases being early inductions in patients not responding to treatment, others being emergencies. In albuminuria cases, the blood pressure is our main guide and where it remains increasingly high, in spite of eliminative treatment, labor is induced.

Finally, instructions as to personal hygiene and care, we believe, prevent many cases of septicemia and mastitis in mothers, with consequent good effect on the infants.

CONCLUSION

I believe we are repaid for continuing our prenatal clinic and striving to improve it; that it is one of the most important features of the obstetric department; that prenatal care, though it seem thankless, has very definite results, and that it is often by such painstaking attention that we accomplish most.

OBSERVATIONS ON INCIPIENT HYPERTROPHY OF THE PROSTATE

ABRAHAM L. WOLBARST, M.D.
NEW YORK

The diagnosis of beginning prostatic hypertrophy is not always a simple matter, particularly in the hands of the general practitioner, and occasionally in the hands of the urologist. Especially is one apt to find these diagnostic errors in cases involving the nervous system, in which functional disturbances of the bladder are the prevailing symptoms. Such errors are liable to occur when one fails to remember that spinal cord disease often gives the first evidence of its existence by the development of disturbances in the urinary and sexual functions. In such cases, it is not to be wondered at that errors occur, but there can be no doubt that they can be reduced to a minimum, even to zero, if due precautions are taken.

CASE REPORT

A case of this kind, which occurred in my experience, illustrates this point rather strikingly:

The patient was a man, aged 49, married twelve years, the father of five healthy children. He had been perfectly well up to a year previously, when he noticed a weakening of the urinary stream, an increased frequency in the desire to urinate, and a delay in starting the stream. His family physician made the diagnosis of prostatic hypertrophy, and took him to a urologist for confirmation. The urologist performed a cystoscopy, found a prostatic enlargement, with bladder trabeculations, confirmed the diagnosis, and recommended prostatectomy. The patient, thoroughly alarmed at the prospect of a surgical operation for an ailment which was not giving him much annoyance, determined to seek another opinion, and thus came under my observation.

The patient was still a young man, physically and mentally, and when he stated that he came for the purpose of confirming the diagnosis and approving of the operative suggestion, the first thought was that this was a young man, indeed, to have his prostate removed, hypertrophy notwithstanding. Cystoscopy was not undertaken; I believe that cystoscopy is not necessary in the diagnosis of prostatic hypertrophy, when other diagnostic elements are available. In this particular case, hypertrophy did not appear probable after the following data were obtained: urine clear, residuum three-fourths ounce, urethral length 7½ inches, no nocturnal call to urinate. The prostate was slightly enlarged by rectum; there was no stricture in the urethra.

Physical examination added something useful to these unsatisfactory data. The knee-jerk was totally absent, pupils dilated unequally, slight Romberg present. Further questioning elicited the information that twenty years previously the patient had a penile ulcer, which soon passed away. He received internal treatment of some kind for about a year, but had not taken any since then. Wassermann, four plus.

With this information at hand, I made a diagnosis of incipient tabes dorsalis, and referred the patient to Dr. Joseph Fraenkel, who confirmed the diagnosis, and under whose care the patient has been doing very nicely for the past two years. At the present writing, the patient does not show any evidence of prostatic hypertrophy, except as stated above.

USE OF THE CYSTOSCOPE

This case teaches us several lessons. First, mere enlargement of the prostate as seen with the cystoscope does not necessarily demand immediate prostatectomy. This will be discussed later on. Secondly, the cystoscope, with all its great usefulness, still has its limitations, and one of these, in my opinion, is in the diagnosis of prostatic hypertrophy. I am conservative enough to rely on the clinical manifestations for the diagnosis of the senile prostate. Given a residuum in the bladder, an increased urethral length, increased desire and frequency, particularly at night, in a man of 50 or over, and the diagnosis is just as certain as any cystoscope can make it. What is objected to is not the use of this invaluable instrument, but its employment as a routine measure in making the diagnosis, when clinical evidence is available.

The literature need not be invoked to confirm the statement that the harm done by the use of the cystoscope in these cases has far more than counterbalanced the good derived by the information which it has furnished. False passages, infections and acute retention are among the sequelae of this practice of employing the cystoscope as a routine measure, in suspected cases of prostatic hypertrophy. Undoubtedly, when the diagnosis is not clear and further enlightenment is desired, the use of the cystoscope is not only permissible, but actually imperative; but the skilful urologist is distinguished by his ability to determine when the use of the cystoscope is merely permissible, and when it is imperative.

The third lesson which this case might teach, if we would learn, is that the physical examination and the serologic test are of the greatest importance in these cases. One might well ask, in this connection, Of what good is the knowledge that the prostate is enlarged intravesically and the bladder trabeculated, when one omits the examination for the knee-jerk, the Romberg, the pupillary reaction and the Wassermann? I think that it is of far greater importance to determine the presence of a spinal lesion and bring it under control, as far as possible, and thereby increase the power behind the urinary stream, than to ignore this possible condition and attempt to relieve the situation by immediate extirpation of the prostate, declared guilty on the sole evidence furnished by the cystoscope.

This brings us to the third point of interest, namely, Should the prostate be removed immediately just because of an enlargement of one or more of its lobes? A search through contemporaneous literature offers very little enlightenment on this question. Writers on prostatic hypertrophy, as a rule, pay more attention to the subject of how to operate than when to operate. Occasionally one finds a vague suggestion that has more or less bearing on this moot point.

From the purely academic and theoretical point of view, it would appear that every prostate showing an enlargement into the urethra or bladder ought to be removed without delay, for surely it will have to be accounted for at some later date, when the patient's general condition may not be so good as when the enlargement is first discovered. On the other hand, when one considers the risk to life attached to the operation, and the frequent unhappy sequelae after operative recovery, one feels that there ought to be something more than mere enlargement to justify so formidable an operation as prostatectomy. In the ultimate analysis, this question is decided, each case on its own merits, by the surgeon and the family physician, for the question of operation must be determined in every case on the existing conditions that call for relief.

So much has been said and written optimistically on the subject of prostatectomy that the general practitioner is apt to consider the operation rather lightly, and urge its performance as soon as the patient makes complaint of his urinary disturbances.

I feel rather keenly in this matter, because of my observations on the results attained after removal of the prostate. I have under treatment, at present, a man, aged 51, who had his prostate removed by an excellent surgeon three years ago, at the age of 48, by the perineal route. At that time, for six months previously he had been complaining of increased frequency of urination and slowness of the stream. He had 1 ounce of residuum, and voided once during the night. Operation was advised and accepted, with the result that the man has become totally impotent and has absolute incontinence of urine, being incapacitated for business because of the persistent odor of urine about his person, and his life has been made miserable generally. In all other respects he is still a fairly young, healthy man, with not a gray hair on his head.

It would appear to have been wiser to give this man an opportunity to rid himself of his symptoms in some manner other than by radical operation so early in life. Prostatectomy is inherently a procedure that should be adopted when other measures fail to afford relief. It is not the first remedy to think of, but the last. When it is clear that palliative measures will not offer relief, prostatectomy is the only remedy that can be advised.

It must not be assumed for a moment that I am advocating the adoption of a catheter life as a prelude to prostatectomy. To the contrary, the permanent use of the catheter for the emptying of the bladder is an anomaly in these days of progressive surgery. Indeed, I am firm in the conviction that the time for prostatectomy has arrived as soon as the catheter has become necessary for emptying the bladder. But that does not mean that prostatectomy is demanded the moment an enlarged prostatic lobe has been discovered. It simply means that prostatectomy is demanded and made necessary when it is seen that the bladder is incapable of emptying itself of its contents. In other words, the indication for operation is not found in the enlarged prostate per se, but in the disturbance of function which such enlargement produces. Surely a man with a prostate as large as a fist is no worse off than his neighbor with a normal prostate, so long as he empties the bladder of its contents and thereby prevents the accumulation of residual urine. Why not give the incipient hypertrophied prostate a chance? We have all seen instances innumerable in elderly men, in which the prostate is large without any or only a slight disturbance in the urinary function. In these cases, the bladder wall is hypertrophied and has become so in response to the increased obstruction at the vesical neck. But if such a bladder empties itself with reasonable satisfaction, it would seem only proper to conserve the prostate and encourage the bladder to continue its work.

This is a very important matter, and deserves greater consideration than it usually receives. It is a problem worthy of our best thought. For several years I have been working along these lines, and I am convinced that prostatectomy might be avoided in many instances, if proper attention is paid to improving the condition of the bladder and the prostate.

At Beth Israel Hospital and in private practice, we have had a large number of incipient prostatics, as they might be termed, who have been treated with the view of increasing the bladder function and thereby counteracting the obstructive tendency of the enlarged prostate. It has been found that in many cases the prostate reaches a certain stage in the hypertrophic process, and then comes to a standstill. In these cases, there may be an ounce or two of residual urine, the urethral length may be one-half inch longer than normal, and the cystoscope may reveal a decided prostatic enlargement, and possibly some trabeculation of the bladder mucosa. But the patient is in a fairly comfortable condition, arising at night once or probably twice to void urine. Patients have gone on this way for five or six years, and sometimes longer, without any increase in the obstructive symptoms, and consequently without any urgent necessity of removing the prostate.

If at any time the obstructive symptoms become more persistent and urgent, prostatectomy is advised as the only means at our command which will restore the urinary function as nearly as possible to its previous condition. But so long as the patient can be kept in reasonable comfort without resorting to the catheter life, operation is not recommended.

TREATMENT

Our treatment includes the administration of a urinary antiseptic, keeping the bowels open, abstinence from alcoholic and sexual excesses, emptying, and irrigating and stretching the bladder once or twice weekly. We find that stretching the bladder gently by filling it to its maximum capacity is of great value, as it stimulates the bladder walls, very much in the nature of massage, thereby maintaining its ability to meet for a long time the increasing demands made on it by the obstructing prostate. Alcoholic and sexual temperance are of great importance in this connection, for we have found that an unusual indulgence will often bring about a sudden increase in the obstructive symptoms. Moderation in all things is the watchword for the incipient prostatic.

CONCLUSIONS

The urinary symptoms associated with incipient prostatic hypertrophy are liable to be confused with functional disturbances of the bladder due to central nerve lesions, such as tabes dorsalis. Every patient with suspected prostatic hypertrophy should be carefully examined for evidence of spinal cord disease. The Wassermann test and the physical examination will often indicate that the urinary disturbances are due to central nerve disease, rather than to prostatic obstruction. The cystoscope is not to be used in the diagnosis of prostatic hypertrophy, unless the clinical data are insufficient. While the cystoscope is usually a perfectly safe instrument in the hands of the expert, it is potentially capable of doing much damage. The diagnosis of hypertrophy should be made on the clinical findings. Prostatectomy should be undertaken as a last resort, and not as a routine procedure. The bladder should be given an opportunity to compensate for the obstruction of the enlarged prostate. This can be encouraged by the application of hygienic measures tending to prevent congestion of the prostate and bladder. Massage of the bladder walls, by gently filling the bladder to its capacity, is extremely useful in stimulating compensatory hypertrophy. Prostatectomy is demanded as soon as a catheter is required to keep the patient in comfort.

EXPERIENCES WITH THE SODIUM CITRATE METHOD OF INDIRECT TRANSFUSION OF BLOOD (LEWISOHN)

IRVING SIMONS, B.S., M.D.
NASHVILLE, TENN.

During the last few years, attempts have been made by numerous workers to discard the direct method of transfusion by suture or cannula (Crile, Elsberg, Bernheim, Carrel) and to replace it by the indirect method on account of: (1) the technical difficulties in the former methods; (2) the time consumed in transfusing, which of course weighed heavily on surgeons, donor and recipient; (3) the impossibility of accurately estimating the amount of blood received by the recipient, and (4) the difficulty, at times encountered, in maintaining the flow of blood for a sufficient length of time, because of the occurrence of thrombosis in the donor's artery, notwithstanding excellent technic.

These attempts at improvement resulted in the indirect transfusion, performed by two groups of methods:

1. Those in which the blood was removed from the donor and transfused hastily into the recipient in small amounts repeatedly until sufficient blood had been transfused. This was done either intermittently (Lindemann) or continuously (Unger) by the syringe method, or by the use of larger paraffined vessels (Curtis, Kimpton). Haste was required in order to prevent coagulation.

2. Those in which substances such as herudin (Hooker, Satterlee), or more recently sodium citrate (Lewisohn), were mixed with the blood to prevent coagulation.

The last-named method would seem to be ideal, because it allows the use of a cheap, easily sterilizable fluid (2 per cent. sodium citrate); the blood remains fluid indefinitely, and can be transported; the amount obtained and transfused can be measured, and the transfusion becomes simplified to an infusion given with a glass infusion bottle and salvarsan needle or infusion cannula. Theoretically, however, there are objections to the method, because it adds something to the blood which is not normally present, it allows the blood to stand in the air outside the body for a certain length of time, and it allows the blood, a tissue which is normally in contact only with endothelium, to come in contact with foreign bodies (glass, rubber and metal). These objections do not pertain in direct transfusion (for example, the Crile method). Whether or not these objections are really valid remains for the future to show. The mortality statistics will decide this.

At any rate, Richard Lewisohn[1] reported twenty-two citrate transfusions on eighteen patients. These patients were transfused with amounts of blood varying between 150 c.c. in children and from 500 to 1,000 c.c. in adults. In no case was any fatality recorded, although they were most desperate cases.

It is the chief purpose of this communication to record the results obtained in three transfusions performed by the Lewisohn citrate method. It is interesting that in this small group we can compare in two of the cases the results of the citrate indirect method and the Crile direct method, as one of them had a citrate followed by a Crile transfusion and the other a Crile followed by a citrate transfusion.

---

[1] Lewisohn, Richard: Surg., Gynec. and Obst., 1915, xxi, 37.

Case 1.—G. D., laborer, seen in consultation with Dr. Francisco, March 12, 1915, had been having painless passages of black blood from the bowel for four or five days. The hemoglobin was 25 per cent. Examination revealed general neurofibromatosis of the skin (von Recklinghausen's disease), no fever and epigastric tenderness. A clinical diagnosis of duodenal ulcer was made. Two days previously, the patient had been transfused with 375 c.c. of citrated blood by Dr. Francisco. After receiving 200 c.c. of blood, the patient became nauseated, retched, his face assumed a drawn expression, cold sweat appeared, and the pulse became thready. He rapidly recovered, and the transfusion was completed. One hour later he went into profound shock, from which he recovered in two hours, and voided claret-colored urine with relief. He was removed to Trinity Hospital, a donor was procured, and I performed a Crile direct transfusion, raising the hemoglobin from 25 to 55 per cent. The duration of the operation was four hours. The patient, previously almost moribund, became quite conscious, and talked logically.

Exploratory laparotomy by Dr. Sharber, one hour later, through an upper median abdominal incision, revealed the stomach and duodenum negative for ulcer. On the anterior aspect of the second part of the duodenum was a firm subperitoneal mass the size of a small olive. It was easily enucleated and the peritoneal rent closed. In the lower part of the ileum, about 1 foot from the ileocecal valve, was another slightly larger subperitoneal mass, situated on the peripheral aspect of the intestines. It was treated in a manner similar to the former tumor. The rest of the abdomen was explored but found negative. In the removal of neither tumor was it necessary to enter the lumen of the intestine.

The patient seemed in good condition the next morning, and had 43 per cent. of hemoglobin, but died at 11 a. m. No claret-colored urine had been voided. According to the pathologic report, the tumor of the ileum was a fibromyoma; and that of the duodenum a fibromyosarcoma. No nerve fibers were shown in Weigert preparations.

Apparently the direct transfusion was successful in this case, while the indirect was not only unsuccessful, but also accompanied by almost fatal shock.

Case 2.—Mrs. J. C. P., seen at Trinity Hospital in consultation with Drs. Sharber and Rieger, was anemic, owing to the bleeding of a fibroid uterus. The hemoglobin was 38 per cent. On this patient, July 13, 1915, I performed a transfusion by the citrate method with 500 c.c. of citrated blood obtained from her husband, whose hemoglobin was 100 per cent. The duration of the operation was fifty-five minutes. The hemoglobin of the recipient rose at once to 58 per cent. One hour later moderate shock followed, but was easily combated, and the temperature rose to 102.6. The next day after purgation and preparation for operation, the hemoglobin was 75 per cent. None had appeared in the urine (by the guaiac test). A supravaginal hysterectomy and bilateral salpingo-oophorectomy was performed. The hemoglobin twelve hours after operation was 60 per cent.

Aside from the combatable shock, the citrate transfusion was unusually successful.

Case 3.—W. W., woman, was admitted to the hospital July 1, with symptoms of sudden intra-abdominal hemorrhage. When seen there in consultation with Dr. C. R. Sharp, the symptoms had somewhat abated. July 3 the hemoglobin was 60 per cent. An indefinite mass was felt in Douglas' culdesac. Menstruation had been irregular. A clinical diagnosis of ectopic gestation with intra-abdominal hemorrhage was made.

The patient was comfortable until the morning of July 5, when she again had signs of hemorrhage. Dr. Sharp performed a laparotomy for ectopic gestation; the right tube and ovary were removed; the patient received two intravenous saline infusions on the operating table, and was removed to the ward in a critical condition. The hemoglobin was 43 per cent. Within two hours I performed a Crile direct transfusion, using the patient's son as donor, and raising the hemoglobin to 51 per cent. The duration of the transfusion was two and one-half hours. No claret-colored urine was voided. The patient apparently did well for one week, but for the next few days had been looking ill. July 16 the hemoglobin was 52 per cent. A citrate transfusion was done with the same donor as before and the same flasks of citrate and saline that had been used in Case 2. Three hundred and fifty c.c. of blood were drawn. As soon as 100 c.c. had run in, the patient became restless and cyanotic, and the pupils dilated widely. She recovered from this, and 100 c.c. more were allowed to run in when she collapsed completely; her mouth twitched, the pupils dilated, the pulse and heart sounds became imperceptible, and cyanosis ensued. The transfusion was stopped. The hemoglobin had risen to 62 per cent. She was given extreme stimulation, but ceased at the end of six hours.

Both the 2 per cent. sodium citrate and the 0.9 per cent. sodium chlorid solutions were made of freshly distilled water and autoclaved at once at 20 pounds' pressure for thirty minutes.

These case reports show that we are not yet in a position to discard the direct for the indirect transfusion. In spite of the difficulties in technic attending the former, I believe it would be better to obtain the services of one skilled in arterial surgery and eliminate such a percentage of reactions (shock) as 100 per cent., and of mortality as 33⅓ per cent. There is no reason to believe that hemoglobinuria may not occur with either type of transfusion with equal frequency; in Case 1 it was responsible for the failure of the citrate method, although neither hemolysis nor agglutination occurred in vitro (Dr. Francisco). Having had an experience of a large number of direct transfusions, I can say that shock is a negligible factor, that infarction occasionally occurs (lung, kidney), and that hemoglobinuria is quite common and can occur even when the tests in vitro are negative.

I have seen tremendous reactions occur after transfusion of cases of bacteremia, possibly due to bacteriolysis. But a fatality in a case of secondary anemia, following direct transfusion by any method whatsoever, I have never yet witnessed.

Therefore, I would heartily condemn any indirect method that depends on the addition of some substance, such as sodium citrate, which will prevent the coagulation of the blood to be transfused.

178 Eighth Avenue North.

American Hospital at Chefoo.—The hospital of the American Presbyterian Mission at Chefoo, China, was completed in the summer of 1914 and is said to rank with the best hospitals in the larger cities of China. It is described by A. Krisel, a student at the mission, in U. S. Commerce Reports. It is situated on a hill overlooking the harbor of Chefoo and has grounds which cover 4 acres enclosed by a high stone wall. The buildings consist of the hospital, a dispensary, isolation wards for men and women, a morgue and a water pumping plant. The total cost of the hospital, including the equipment, was about $50,000 gold. It is built of brick and stone and is three stories high. It measures 160 by 128 feet and there are 8 ward rooms and 8 private rooms with a total of 35 beds; the capacity can be increased to 50 beds, accommodating about 400 patients in the year. The hospital building is heated by a low pressure steam plant and has electric lights. A Roentgen-ray apparatus has been purchased in the United States. Water is secured from a bored well 200 feet deep; wastes are disposed of by the septic tank system. The hospital had, at the time of the report, two foreign and one Chinese physicians, one foreign and one Chinese female nurses and eight Chinese male nurses. It was then running at about one third its capacity.

STUDIES ON THE LOCALIZATION OF CEREBELLAR TUMORS

III. POSTERIOR NEW GROWTHS WITHOUT NYSTAGMUS *

ERNEST G. GREY, M.D.
Assistant Resident Surgeon, Peter Bent Brigham Hospital
BOSTON

INTRODUCTION

The purpose of this study has been to determine the proportion of patients with certified subtentorial new growths who have shown no nystagmus previous to operative treatment.

Practically all authorities agree that nystagmus is a valuable localizing sign in diseases of the posterior cranial fossa. To this category belong especially lesions of the cerebellum, the cerebellar peduncles, the vestibular nerves, the neighboring nuclei and the labyrinths. When general pressure symptoms suggest the presence of a tumor, nystagmus assumes more importance still, for it is recognized that the occurrence of this sign in a patient with symptoms of subtentorial new growth argues in favor of an extracerebellar or intracerebellar neoplasm. Stewart and Holmes[1] hold that this sign is almost invariably present in every case of cerebellar tumor at one or another time.

Occasionally, however, in patients of this type no discernible rhythmic movements of the eyes are found on repeated investigation. Though frequently other features of the examination suffice for purposes of diagnosis,[2, 3] there are instances in which the localization of an intracranial tumor in the posterior fossa is a very difficult problem.

A case in point recently came to my attention (table, 2320). The patient was examined repeatedly and by different observers, but no suggestion of nystagmus ever was noted. The picture as a whole was quite obscure. A tentative diagnosis of subtentorial tumor finally was made from the rapid onset of pressure signs (advanced choked disks, areas of absorption and enlarged venous channels in the roentgenograms, etc.) and the history of some disturbances in gait. There were no further significant localizing signs. Operation disclosed a solitary, median tubercle of the cerebellum measuring approximately 3 cm. in diameter.

When confronted with problems of this sort it is a matter of some importance to know the relative proportion of patients with certified cerebellar tumors who show no nystagmus previous to operative treatment. With information of this nature conclusions may more easily be drawn regarding the advisability of suboccipital exploration.

The records used in this analysis are from patients with tumors in the posterior fossa who have appeared in the neurologic services of Dr. Cushing at the Johns Hopkins Hospital previous to September, 1912, and at the Peter Bent Brigham Hospital since that date. Most of the cases in the latter group were personally studied by me. Of several hundred such cases only those—fifty-one in number—in which the new growths were localized at operation or at necropsy have been used for this report. In addition, for purposes of comparison, the records of forty-one patients from the latter clinic with verified supratentorial tumors have been analyzed for the presence or absence of nystagmus.

Practically all of the patients were studied by more than one observer. This method of checking up the routine examinations is significant, particularly for the patients reported as showing no nystagmus.

As Wilson and Pike[4] have pointed out, the word "nystagmus," in its present usage, is an indefinite term covering various types of ocular movements arising from lesions in diverse parts of the nervous system. Though these have been frequently differentiated into several distinct types, English writers have generally applied the term to oscillations of the eyes without distinction in regard to the variety of the movements. In this analysis no patient has been classified in the group without nystagmus if jerks were discovered at any time exceeding physiologic limits.

CASES OF CEREBELLAR TUMORS WITHOUT NYSTAGMUS

Of fifty-one cases of verified subtentorial new growths, there were eleven in which no nystagmus was discernible previous to operation. Nystagmus was absent in one additional case on repeated examination up to the day of exploration (table, 357). For purposes of comparison these are presented in the accompanying table.

The lesion concerned in eight of the cases was a glioma or a gliomatous cyst. In three there were tuberculomas, two being solitary. As regards the site of the new growths, it is seen from the table that they involved practically all portions of the cerebellum. Either the right or left hemisphere was affected as a whole or in part in six cases. The tenth and eleventh patients showed an involvement of both the vermis and an entire hemisphere. In the twelfth the lesion affected the deeper, anterior portion of the vermis and the right lobe. It is noteworthy that in no instance was the cerebellopontine angle primarily involved.

The degree of intracranial pressure varied widely among these patients. From a case with no measurable swelling of the optic nerve head and only moderate tension at operation, the pressure ranged to one with advanced choked disk and extreme herniation of the cerebellum into the spinal canal.

Accessory measures for eliciting nystagmus were tried in three of the patients—moving the head as first suggested by Oppenheim,[5] and using opaque spectacles as recommended by Bárány.[6] No success attended any of these tests.

The importance of making repeated observations is well shown by Case 357, in which a fine nystagmus finally appeared just previous to the operation.

The records of two patients illustrate how nystagmus which has been absent during one period of study may appear in later examinations subsequent to a suboccipital operation. Patient 30,000 on the second admission and Patient 357 on the second and third admissions had characteristic rhythmic movements of the eyes.

CASES OF CEREBELLAR TUMORS AND NO NYSTAGMUS

Patient	Lesion	Intracranial Pressure	Tinnitus and Hearing	Dizziness	Eye Muscles	Caloric Test	Nystagmus
2320 ♂ 22	Tuberculoma involving vermis principally; rt. hemisphere slightly. (Operation.) Tumor about 3 cm. in diameter.	Choked disks 4-5 D. Marked tension at operation. Extreme herniation of cerebellum into spinal canal. Int. hydrocephalus.	No tinnitus. Hearing good. Slightly less acute rt. ear.	Some. No rotation of objects or self.	No strabismus. Conjugate deviations good. Very slight restriction toward pt's. left.	Definite nystagmus from irrigation either ear. More marked from left. Normal pointing reactions. Reaction movements from both sides.	None with eyes directed forward, to either side, up and down, on changing position of and shaking head, or on breaking fixation.
1406 ♂ 45	Tuberculoma of left hemisphere. (Necropsy.) Tumor about 3 by 2.5 by 2 cm.	Choked disks 6-7 D. Marked tension at operation. Herniation into spinal canal.	No tinnitus. Hearing less acute in left ear.	None	No strabismus. Conjugate deviations good.		None with eyes directed forward, to either side, or up and down.
320 ♀ 6½	Glioma involving vermis and medial portion of each hemisphere. (Operation and necropsy.) Tumor 4.5 by 3.2 cm.	Advanced choked disks. Marked cerebellar herniation into spinal canal. Int. hydrocephalus. Pons and medulla distorted.	No tinnitus. Hearing normal.	None	No strabismus. Conjugate deviations good.		None with eyes directed forward, to either side, or up and down.
27738 ♂ 41	Cyst involving left hemisphere principally. (Operation.) Cavity about 5 by 4 by 4 cm.	Choked disks. Moderate tension of dura and cerebellum at operation.	No tinnitus. Hearing normal.	(?)	Slight weakness left internal rectus.	Definite nystagmus from irrigation either ear. Normal vestibular response, both sides.	None with eyes directed forward, up and down, or to the right. A few atypical jerks on looking to the left.
1444 ♂ 43	Multiple small tuberculomas involving vermis and left hemisphere. (Necropsy.) Largest 1 cm. in diameter.	Early choked disks 1 D. Moderate tension at operation. Probably slight int. hydrocephalus.	No tinnitus. Hearing about normal.	Marked dizziness. No rotation of objects or self.	No diplopia or strabismus. Some weakness left ext. rectus (?).	Marked nystagmus within very short time from irrigation either ear. Normal pointing reactions and reaction movements.	In two examinations atypical jerks of brief duration appeared only when looking to either side. Subsequently no jerks or nystagmus on directing eyes ahead, to the sides, and up and down. None on moving head and on breaking fixation.
1642 ♀ 64	Cyst (gliomatous ?) involving rt. hemisphere principally. (Operation.)	Very early changes in eye-grounds. Hyperemic. No elevation. Moderate tension at operation.	No tinnitus. Hearing normal.	Marked. No rotation of objects or self.	No diplopia or strabismus. Conjugate deviations good.	Marked nystagmus within very short time from irrigation either ear. Normal pointing reactions and reaction movements.	None with eyes directed forward, to either side, up and down, on moving head, or on breaking fixation.
51 ♂ 8	Cyst (gliomatous ?) involving rt. hemisphere principally. (Operation.) 42 c.c. fluid from cyst.	Choked disks with secondary atrophy. Int. hydrocephalus marked. Separation sutures. Marked tension at operation. Great herniation into spinal canal.	No tinnitus. Hearing normal.	None (?)............	Some diplopia. No strabismus. Conjugate deviations good.		None with eyes directed forward, to either side, or up and down.
107 ♀ 3½	Cyst (gliomatous) involving rt. hemisphere principally, also vermis. Includes nearly whole rt. hemisphere. (Operation.)	Early choked disks. Marked int. hydrocephalus. Great herniation into spinal canal.	Tinnitus (?). Hearing about normal.	(?)	No diplopia or strabismus. Conjugate deviations good.		None with eyes directed forward, to either side, or up and down.
30000 ♀ 6	Large cyst (gliomatous) occupying left hemisphere principally. (Operation.)	Choked disks 5-6 D. Int. hydrocephalus. Marked herniation into spinal canal.	No tinnitus. Hearing less acute in rt. ear.	None (?)............	Paralysis left abducens. Very slight weakness rt. abducens (?).		None with eyes directed forward, to either side, or up and down.
357 ♂ 36	Glioma involving anterior portions, rt. hemisphere and vermis. (Operation.)	Choked disks 5 D. Marked tension at operation. Herniation into spinal canal.	Some tinnitus each ear. Hearing normal.	Fairly marked. No rotation of objects or self.	History of diplopia. No strabismus. Conjugate deviations good.	Slight nystag. from rt. ear; marked from left. Reaction movements only from left ear. Pointing errors to right both arms.	None with eyes turned in all directions on numerous examinations. Just previous to operation a fine, indefinite nystagmus appeared on looking to either side.
151 ♀ 9	Large cystic glioma involving rt. hemisphere principally, also vermis. (Operation.)	Advanced secondary optic atrophy. No elevation. Hydrocephalic configuration of skull. Marked pressure at operation. Int. hydrocephalus.	No tinnitus. Hearing normal.	None	No diplopia. No strabismus. Conjugate deviations good.		None with eyes directed forward, upward, or to her right. Some atypical coarse jerks on looking toward her left.
26387 ♀ 37	Cystic glioma involving left hemisphere principally. (Operation.)	Choked disk. Moderate tension at operation. Int. hydrocephalus.	Considerable tinnitus rt. ear. Later left ear. Hearing normal.	Some	No diplopia. No strabismus. Conjugate deviations good.	No nystagmus provoked on irrigating either ear. No subjective distress.	None with eyes turned in all directions.

Two of the patients complained of tinnitus and three showed a slight homolateral reduction of air conduction. These complications had appeared during the present illness in each case. Functional tests, however, disclosed no serious impairment of the eighth nerve in any instance.

CASES OF CEREBELLAR AND EXTRACEREBELLAR TUMORS WITH NYSTAGMUS

While tumors may arise in every possible position in the posterior fossa, it is convenient for purposes of localization and surgical treatment to consider them as occupying four principal regions, two within and two external to the cerebellum. In regard to the former we may speak, first, of the tumors which occupy a central position, that is, those which involve the vermis and more or less of the median portion of each lateral lobe; and, second, of those which lie wholly within one or the other hemisphere. In reference to the latter we may look on the new growths either as occupying the cerebellopontine angle, or as lying more or less between the posterior portions of the lateral lobes, dorsalward from the medulla and vermis.

There were thirty-nine verified cases of tumors occupying one or the other of these regions in which nystagmus was present previous to operative treatment. In twenty-two the new growths were intracerebellar; ten occupied a median position, while eleven lay in one lateral lobe. In one there were gliomatous cysts in both hemispheres. The size of the new growths varied greatly, from lesions with a diameter of a few centimeters to growths which replaced most of the cerebellum. An extracerebellar tumor was found in each of seventeen patients. Of these tumors thirteen occupied a unilateral cerebellopontine site and three a posterior, median position. In one additional case an infiltrating glioma of the vermis lay partially exposed in the posterior, median sulcus.

The degree of intracranial pressure in this group was found to vary within wide limits. In several instances the eye-grounds appeared to be practically normal. Operation disclosed only a moderate tension of the suboccipital structures. In the balance of the cases, on the other hand, the changes in the optic nerve-head varied from a few diopters swelling to an advanced choking of the disk. A number of the patients showed marked secondary atrophy. At operation corresponding differences were noted in the degree of internal hydrocephalus.

The experiences with the caloric test and the pointing reaction (Bárány) in these patients have been discussed in another place.[7]

THE PRESENCE AND ABSENCE OF NYSTAGMUS IN CASES OF TUMORS LYING ANTERIOR TO THE CEREBELLUM

Nystagmus is sometimes found in patients with new growths lying anterior to the cerebellum. As its presence here is always confusing, this has somewhat limited its usefulness as a sign of disease in the posterior fossa. The types of nystagmus in the two classes (that is, patients with tumors lying anterior to the cerebellum and those with cerebellar or extracerebellar growths) are occasionally identical. In each the movements may be fine and inconspicuous or they may appear as coarse, well-marked jerks. It is frequently impossible, even, to recognize the variety arising from direct irritation in the labyrinth; for, as Friesner and Braun[8] have pointed out, despite much that has been said to the contrary, the nystagmus due to cerebellar disease often cannot be differentiated clinically from that due to labyrinthine disease. Our experience has been that on the average the movements are coarser and more marked in individuals with lesions situated below the tentorium.

The fact that no nystagmus was noted in fully one third of the cases of intracerebellar new growths suggested a similar analysis of the cases with verified lesions lying anterior to the cerebellum in order to determine the relative frequency of this sign in the latter group.

Of forty patients with tumors situated anterior to the cerebellum, eight showed characteristic rhythmic oscillations of the eyes previous to any surgical interference. The new growths and their locations were as follows: one glioma, right occipital lobe; one glioma, right thalamus principally; one gumma, left temporal lobe; two cases of gliomatous cyst, one right and one left, parietal lobes; one solitary tubercle and one glioma, pons; and one hypophysial cyst.

The caloric test was used on three of the patients—occipital lobe glioma, thalamic glioma, and pontine tubercle. In each a typical nystagmus appeared following the irrigation of either ear.

There were thirty-two individuals in whom no nystagmus was detected; one gumma and one glioma, left frontal lobe; one gliomatous cyst, right frontal lobe; one endothelioma, pons; one glioma, left thalamus; two cases with a glioma each, and two with an endothelioma each, right parietal lobe; one glioma, left parietal lobe; two patients with a glioma each, and one with a gumma, left temporal lobe; one gliomatous cyst, one glioma, and one endothelioma, right temporal lobe; one glioma involving both thalami, right principally; one endothelioma, right temporoparietal region; one endothelioma at the foramen magnum; one metastatic melanotic sarcoma—multiple in cerebrum and cerebellum; and eleven patients with hypophysial strumas or cysts.

Seven of the patients were examined with the caloric test. Typical nystagmus appeared following the irrigation of each ear in six of these: unilateral thalamic glioma, frontal gumma, bilateral thalamic glioma, temporal endothelioma, endothelioma at foramen magnum, and parietal endothelioma. In the seventh—a pontine endothelioma—there was no response from either labyrinth. An involvement of the third, fourth and sixth nerve nuclei probably was largely responsible for this, as voluntary conjugate deviation of the eyes was practically impossible in all directions.

A study of the eye-grounds showed no uniformity in the ophthalmoscopic pictures. The changes in the nerve-head varied in both classes of cases (patients with and patients without nystagmus) from fundi with no measurable elevation to advanced choked disk. A similar variation was pointed out in discussing the cases of intracerebellar new growths (table, column 4).

DISCUSSION

In seeking an explanation for the presence or absence of nystagmus in patients of this class it is necessary to consider briefly the present conceptions regarding the mechanism of nystagmus. These, unfortunately are somewhat discordant. Bauer and Leidler[9] believe from their experiments on animals that nystagmus appears as a result of lesions in the region of Deiters' nucleus—the horizontal jerks more from the ventrocaudal part, and the vertical jerks from the oral part. In a similar way Bárány[10] assumes a nystagmus center here and explains the presence of this and certain other so-called cerebellar signs as the result of increased tension in the posterior fossa. Tumors in any location, as soon as they exert pressure on the posterior fossa, may give rise to an intracranial type of nystagmus, which may be transitory and of varying intensity or permanent and of constant intensity. Hesse,[11] however, questions whether we are justified at present in attributing such signs to the distant effects (*Fernwirkung*) of space-consuming new growths in the large and small brain.

[8] Friesner and Braun: The Functional Tests of the Static Labyrinth in Neurological Diagnosis, New York Med. Jour., 1914, c, 369.

Wilson and Pike,[4] on the other hand, do not subscribe to this or to the various other hypotheses which recognize a nystagmus center. They conclude that an agency somewhere produces a deviation of the eyes from the primary position of equilibrium. In labyrinthine nystagmus this agency lies in the labyrinth. The internal rectus muscle on the side of the slow deviation and the external rectus on the side opposite are subjected to a greater strain than usual. This strain, resulting in the stimulation of the sensory or afferent endings of the eye muscles, sets up afferent impulses which are conveyed to the cerebrum over the afferent fibers in the third, fourth, and sixth cranial nerves.[12] These afferent impulses, in their turn, set up efferent impulses in the oculomotor cells of the cerebrum, which result in a quick, jerky contraction of the internal rectus on the side of the slow deviation and of the external rectus of the opposite side, with relaxation of the antagonistic muscles. The effect is a restoration of the eyes to the primary position. The complex motor mechanism of the eyes, these authors conclude, cannot be described in terms of circumscribed isolated centers, but must be defined in terms of an integrative system.

Mills and Weisenburg[13] regard the nystagmus seen with cerebellar lesions as due to an involvement of the vestibulocerebellar apparatus, probably of the parts connecting the vestibular nuclei with the deep nuclei of the cerebellum.

We are acquainted with the agency connected with the labyrinthine type of nystagmus of which Wilson and Pike speak, but as yet are more or less unfamiliar with that responsible for the development of nystagmus from other portions of the brain. Just what relation the cerebellum bears to the development of rhythmic movements of the eyes is at present rather uncertain. The cerebellum, it appears, has no pathways or centers indispensable for the appearance of either the slow or the quick component. From the investigations of Bauer and Leidler[9] it is clear that while destruction of parts of the cerebellar hemisphere and vermis never causes spontaneous nystagmus, lesions of the latter, nevertheless, result in an excessive excitability of the vestibular nuclei. This has led these workers, with Bárány, Neuman and others, to the belief that in cerebellar disease the nystagmus is due to an alteration in function of the vestibular nuclei or their connections with the nuclei of the eye muscles through pressure.

Oppenheim,[14] with Bruce, Wallenberg, Adler, Probst, Babinski, Horsley and others, assumes a nystagmus of cerebellar origin. Horsley,[15] for example, has shown that a careful electrical stimulation of the white matter in the neighborhood of the dentate nucleus, or of the body of the dentate nucleus itself, provokes a horizontal nystagmus toward the side excited. According to this view, as Babinski[16] has pointed out, nystagmus can be caused by either a labyrinthine or a cerebellar irritation. Rothmann,[17] on the other hand, from excitation experiments of his own, is led to dispute such an influence of the cerebellum on the eye muscles.

In considering the various hypotheses which have been advanced to account for the appearance of nystagmus in patients with intracranial tumors, it is evident that there is nothing in these views which will satisfactorily explain the absence of nystagmus in the series reported here. It has already been pointed out that of thirty-four patients with verified intracerebellar new growths, at least one third showed no nystagmus. Now in both of these groups—that without rhythmic movements of the eyeballs as well as that with them—the same differences were found in the degree of intracranial tension. In both there were patients with very little changes in the eye-grounds and with only moderate tension of the cerebral structures at operation; there were also patients with advanced choked disks and marked herniation of the cerebellum into the spinal canal. A similar variation was noted in the situation of the new growths.

On consulting the table it is clear that the absence of this sign cannot be accounted for by a paralysis of the eye muscles. In eight of the twelve patients practically normal conjugate movements were possible in all directions. Three showed a slight weakness of one external rectus muscle, but this degree of paresis is very frequently noted in patients who show characteristic oscillations of the eyeballs. In only one instance was a complete paralysis of the abducens found. Parallel movements of the eyes were possible here in each of the other directions.

Probably the most important evidence that the absence of nystagmus was not due—in a number of these cases at least—to an impairment of the fundamental mechanism of nystagmus is afforded by the results from the caloric tests. Caloric examinations made in six of the twelve patients showed well-marked nystagmus following the irrigation of each labyrinth in five.

On contrasting the group of subtentorial tumor cases having nystagmus with the group showing no nystagmus, it is evident that rhythmic oscillations of the eyes were found in every patient with an extracerebellar new growth. It should be mentioned, however, that the nystagmus was rather inconspicuous in the cases of posterior, median growths. In one instance the fine, rapid jerking of the eyeballs was noticed only when the patient looked toward his right side. The nystagmus in all of the cerebellopontine cases was well marked. Though the number of cases used in this study is comparatively small, one feature is sufficiently prominent to suggest a generalization. The results from the analysis would seem to indicate that when a patient exhibits a cerebellar tumor syndrome without nystagmus, the absence of rhythmic movements of the eyes points toward an intracerebellar localization of the lesion.

There are several explanations which assist in accounting for the presence and absence of nystagmus in patients with supratentorial new growths. Bárány[10] believes that in such cases it is due to pressure exerted on the nystagmus centers—in the region of Deiters' nuclei—by the tumors from a distance (*Fernwirkung*). When the growths are not space-consuming, however, and lead to no increased intracranial tension, rhythmic oscillations of the eyes do not appear. Another suggestion is offered by Bauer and Leidler.[9] They have shown experimentally that after cerebral hemisphere extirpations there is an increased excitability of the corresponding eye muscle nuclei. It is conceivable that certain cerebral tumors may lead to such a result.

Certain experiments of Wilson and Pike[4] are interesting in this connection. They removed various areas of the cortex, frontal, parietal, occipital, and temporal and also destroyed the subcortical ganglionic masses in cats, dogs and monkeys in an attempt to find some region in a hemisphere where a lesion will modify or abolish labyrinthine nystagmus. The only place where they obtained consistent alteration of the labyrinthine stimulus, and that only so far as the quick component was concerned, was in the region of, or adjacent to, the temporal lobe.

A review of the clinical findings in the patients with supratentorial tumors shows that both the quick and the slow phases of nystagmus may exist in patients with new growths occupying very diverse regions in the cerebrum. In six of the seven patients examined with the caloric test (no spontaneous nystagmus) characteristic rhythmic movements of the eyes appeared following the irrigation of either meatus. In the seventh patient there was almost a complete ophthalmoplegia. Similar results were obtained from patients who showed spontaneous nystagmus. The caloric test was used in three of this group and in each case typical nystagmus followed the stimulation of either labyrinth.

SUMMARY

Of the thirty-four verified cases of cerebellar tumor and seventeen verified cases of extracerebellar tumor, eleven showed no nystagmus previous to operation on repeated examination. All of the cases in which it was absent contained intracerebellar new growths—32 per cent. of the intracerebellar series. This suggests that when a patient exhibits a cerebellar tumor syndrome without nystagmus, the absence of rhythmic movements of the eyes points toward an intracerebellar localization of the lesion.

Among the members of both groups (that is, the group with and the one without nystagmus) there were marked differences in the degree of intracranial tension. In each group there were new growths which involved the vermis and others which replaced a part or the whole of one or both hemispheres.

Caloric examinations made in six of the cases in which there were no rhythmic movements of the eyes resulted in characteristic nystagmus from either labyrinth in five.

Of forty verified cases of tumors lying anterior to the cerebellum, eight showed nystagmus previous to operation. Caloric examinations made in seven of the cases without nystagmus provoked characteristic rhythmic oscillations of the eyes from either labyrinth in six.

These results indicate that in many cases of intracranial tumor the absence of nystagmus cannot be accounted for by an impairment of the fundamental mechanism of nystagmus.

THE DIAGNOSIS OF TUMORS IN THE POSTERIOR CRANIAL FOSSA *

T. H. WEISENBURG, M.D.
PHILADELPHIA
AND
PHILIP WORK, M.D.
PUEBLO, COLO.

Our knowledge of cerebellar symptoms and of cerebellar localization has advanced considerably during the last few years, chiefly owing to the work of Babinski and Rothmann, but in comparison with *cerebral* symptomatology and localization this progress has not been great. This is mainly because clinicians have not studied their cases with sufficient care, and when diagnosing tumors in the posterior cranial fossa have been satisfied with gross diagnoses.

Recently one of us, with Dr. Mills,[1] in a paper on cerebellar symptomatology and localization, reviewed most of the literature on this subject, both foreign and American. In only a few cases was any attempt made to differentiate cerebellar symptomatology to any of the limbs or parts of the trunk, while a study of the pathologic reports was equally disappointing; most writers were satisfied with the assertion that either one or both lateral lobes or the vermis was implicated, there being few definite statements of the particular part of the cerebellum diseased.

It is advisable, therefore, briefly to state our views on cerebellar localization and cerebellar symptomatology. We have adopted the tentative localization advanced by Mills and Weisenburg. It is probable that many of their views are wrong; but it is necessary to make a start, and the localization advanced by them is perhaps as comprehensive as can be made at the present time. To arrive at a definite conclusion it is necessary for all clinical and pathologic reports to be accurate and complete, so as to leave no doubt as to what part of the cerebellum is implicated.

We believe that the chief function of the cerebellum is to synergize all movements of the body. Whatever symptoms are present, such as hypermetry, adiadokocinesis or tremor, result from loss of synergy. This asynergy can be detected in any part, or parts, of the body. It may be present in one limb, the limbs of one side, in the upper limbs and shoulder girdle, in the lower limbs and the pelvic girdle, or in all parts of the body. Not only that, but in the development of these symptoms it is possible to tell whether the lack of synergic movement in the upper limb, for example, is in abduction or adduction, or in upward or downward movement. The methods of elicitation have been carefully described in the paper previously referred to. We wish to emphasize here that it is possible to differentiate cerebellar asynergy in parts of the body.

[1] Mills, Charles K., and Weisenburg, Theodore, H.: Cerebellar Symptoms and Cerebellar Localization, Including Kinematographic Observations on Cerebellar Phenomena, The Journal A. M. A., Nov. 21, 1914, p. 1813.

We have found the Bárány method of investigation of great value in the differentiation and elicitation of symptoms. By means of the caloric tests and the turning tests, it is possible to demonstrate by direct stimulation of the vestibular apparatus the presence or absence of certain phenomena. This subject was presented by one of us in association with Dr. I. H. Jones, before the recent meeting of the American Neurological Association in New York.

In presenting this subject, we first discuss lesions confined strictly to the cerebellum; second, lesions implicating the superior cerebellar peduncle; third, lesions involving the middle cerebellar peduncle; fourth, lesions implicating the inferior cerebellar peduncle; fifth, lesions of the cerebellopontile angle; and last, lesions invading the cerebellopontile angle secondarily.

We desire to emphasize that, to make an accurate diagnosis of a cerebellar lesion, it is necessary to take into consideration not only the cerebellar symptoms, but all other symptoms. We have been repeatedly impressed with this fact since our attention has been more especially directed to this subject. Often we have made a diagnosis of a lesion of the labyrinth, only to find the cerebellum implicated, and vice versa; again we have diagnosed cerebellopontile-angle tumors only to find that the angle was secondarily invaded by a lesion growing from the cerebellum. It has not been infrequent to diagnose lesions of the cerebellum when the tumor has been in the third ventricle and has involved the superior cerebellar peduncles secondarily.

DIAGNOSIS OF LESIONS STRICTLY CONFINED TO THE CEREBELLUM

In accordance with our views of cerebellar function, lesions of the cerebellum itself cause more strictly limited symptoms than those which invade any of the peduncles. Most tumors of the cerebellum are gliomatous and are of slow growth. The majority tend to invade the middle rather than the outer portions of the cerebellum, and as a consequence, the vermis is nearly always involved wholly or in part, in addition to one of the lateral lobes. We believe that in the superior vermis are centered the synergic movements of the upper trunk or shoulder girdle and in the inferior vermis the movements of the lower trunk or of the pelvic girdle. As a consequence there will always be in such lesions, in addition to disturbances in the movement of one or both limbs, alterations in the station and gait.

There is a great difference in the station and gait in those cases in which the shoulder or the pelvic girdle is implicated. In the shoulder girdle cases, both in standing and in walking the feet are not held widely apart nor is there a swaying of the pelvis. The chief difficulty is that the moment the patient attempts to stand or to walk, his trunk leans or falls forward, backward or to one side very markedly, and *much more so* than in the pelvic girdle cases, for in the latter, because of the inability to synergize the movements of the lower trunk with the legs, the difficulty in walking is much greater, the legs are held farther apart, and instead of the patient lurching to one side, forward or backward, the gait is more irregular, the body is held more erectly, and in walking the legs are projected in front of the patient, showing clearly the lack of synergic action between the trunk and limbs. When the shoulder and the pelvic girdle are both involved, it is sometimes almost impossible for the patient to stand or to walk without aid.

A very good way of differentiating shoulder and pelvic involvement is to place the patient on the floor on the hands and knees. While in such a position, if the pelvis be implicated, there will be very marked to and fro swaying of this part, the shoulders remaining practically still, whereas in the other type the pelvis is held steadily, but the head and shoulders sway and deviate to the side of the lesion.

In cases in which the vermis is implicated, the staggering is mainly forward or backward, rather than to one side, and of such cases, it is more marked in the shoulder girdle type. In our experience, if in addition to the involvement of the vermis, the lateral lobes are implicated, the sway of the trunk is to the side of the lesion, although it must not be forgotten that in a progressive cerebellar disease, the patient may learn, for example, to go voluntarily to the left to offset his staggering to the right.

In those instances in which the lateral lobes alone are implicated, the asynergic movements are present only in the limbs of the involved side: if in the superior lobe, in the upper limb, and if in the inferior lobe, in the lower limb. By direct stimulation of the vestibular apparatus it is possible to obtain, for example, a total lack of outward pointing or inward pointing, whereas this is not so readily demonstrated by the ordinary tests.

Nystagmus.—The question whether nystagmus should or should not be present in cerebellar lesions has by no means been settled. According to our views of cerebellar localization we place the synergic center for eye movements in the extreme upper portion of the superior vermis. It is a well-known fact that in chronic lesions strictly confined to the cerebellum, involuntary nystagmus may be present. One very marked case of this type has been carefully studied by means of moving pictures, and was referred to in the paper with Dr. Mills. In this case the nystagmic movements were constant and in all directions—upward, downward, laterally and in a rotatory direction. We regarded these ocular movements as an example of direct cerebellar ocular asynergy. Other examples of nystagmus are found in diseases of the Friedreich's ataxia type. Rarely involuntary nystagmus occurs in progressively developing tumors, but this is not the rule.

If, however, nystagmus be developed by voluntary movement, the lesion is probably extracerebellar. It is especially in these cases that direct stimulation of the vestibular tract demonstrates the true source of such nystagmus. If, for example, the right ear is stimulated by cold water, there will be obtained quick jerking movements of the eyeballs to the opposite side with a slow return to the same side. The slow recoil to the side of the stimulation is the cerebellar movement, while the quick jerk to the opposite side is the cerebral component. The same results will be obtained if the vestibular apparatus be stimulated by means of the turning chair.

In such tests the impulses go from the labyrinth by the vestibular nerve to the three paracerebellar nuclei — Deiters', von Bechterew's, and triangular nuclei—and thence to the nuclei of the third, fourth, and sixth cranial nerves by the posterior longitudinal bundle, and then to the cerebral cortex. If there be any interruption of this arc, normal nystagmus is not obtained. The location of the lesion will depend on the associated symptoms. If in the eighth nerve there will also be loss of hearing; if in the paracerebellar nuclei, no deafness, but there may be some implication of either the fifth, ninth or tenth cranial nerves, inasmuch as these nuclei are in the outer upper portion of the medulla. If the lesion is in the pons or crus, there may be in addition to the sensory and motor symptoms, involvement of either the seventh, sixth, fifth, fourth or third cranial nerves, with paralysis of associated ocular movement.

Apparently then, the conclusions to be drawn regarding ocular movements are as follows: Involuntary nystagmus is nearly always cerebellar, but voluntary nystagmus is the result of implication of those fibers which are in relation to the vestibular apparatus outside of the cerebellum.

General Symptoms.—The presence of cranial nerve symptoms, as of the seventh, sixth, fifth, ninth, tenth or twelfth, indicates that the lesion is extracerebellar. Dizziness with disturbance of hearing is the result of implication of the vestibular apparatus somewhere in its course and is not a cerebellar symptom. Involvement of the motor fibers, with paresis of the limbs, increased reflexes and Babinski, indicates that there is pressure on the motor apparatus and should not be expected in lesions strictly confined to the cerebellum, except in those cases in which the lesion is very large. As a rule, motor involvement indicates a pontile lesion or a lesion in the angle pressing on the pons. Headache, nausea, vomiting, and choked disk, are, of course, early manifestations, but only in those instances in which there is interruption in the flow of the cerebrospinal fluid, and generally indicate a lesion either in the crus or pons pressing on the aqueduct of Sylvius.

LESIONS OF THE CEREBELLAR PEDUNCLES

We possess little definite knowledge of the functions of the fibers in the cerebellar peduncles. It is supposed that the inferior and middle peduncles transmit impulses to the cerebellum, and that the superior peduncle transmits impulses from this organ. It is probable, however, that all the peduncles transmit impulses in both directions. It is also probable that the inferior peduncles are concerned chiefly with synergic movement of the lower limbs, and to a lesser extent of the upper limbs, the middle peduncle with the synergic movement of the trunk and head, and that the superior peduncles are mainly concerned with the association of cerebral with cerebellar functions. All this, however is theory, based somewhat on anatomic and physiologic facts, but not as yet supported by pathologic and clinical data.

In the literature there are a few instances of lesions confined more or less to one of the peduncles, but it cannot be said that our clinical experience is such that we can differentiate the asynergy resulting from lesions of the superior from those of the middle or inferior peduncles. From our present knowledge all we can say is that lesions strictly confined to any of the peduncles cause asynergic symptoms in all parts of the body and as a consequence we are compelled to make the diagnosis not on the cerebellar symptoms but on those associated with them.

There are instances in the literature in which so-called turning or rolling movements have been recorded in tumors of the middle and of the inferior peduncles, either toward or away from the side of the lesion. These cases, however, are not definite and cannot be relied on. There is, however, this difference in the cerebellar symptomatology of the different peduncles: Because of the anatomic relation of the superior peduncles, lesions of this part invade mostly both sides, the cerebellar symptoms being present all over the body, although rarely, as in the case reported by Mills[2] in which there was thrombosis of the superior cerebellar artery, the asynergy is limited only to the limbs on one side.

The middle cerebellar peduncles being more widely separated, such lesions are often unilateral, whereas tumors implicating the inferior cerebellar peduncle are almost always one-sided.

Tumors of the Superior Cerebellar Peduncles.—In most instances tumors invading these peduncles grow from the third ventricle through the aqueduct of Sylvius, often bisecting the cerebral peduncle and pressing on or destroying one or both red nuclei. In such cases the symptoms consist of a gradually developing paralysis of associated ocular movement upward, and if the lesion extend laterally, central disturbance of hearing on one or both sides, because of the involvement of the posterior corpora quadrigemina. There may be also partial weakness of both upper and lower limbs with the presence of increased reflexes and the Babinski phenomenon. The symptoms resulting from extension of tumors from the third ventricle into the aqueduct of Sylvius were discussed by one of us.[3] Since then we have seen a number of such cases both clinically and pathologically. Because of the preponderant cerebellar symptoms they are nearly always diagnosed as cerebellar, but with the gradual onset of paralysis of associated ocular movement upward the diagnosis is no longer in doubt.

Rarely, as in the case previously referred to,[2] there is thrombosis of the superior cerebellar artery. In such instances there will be loss of unilateral emotional expression in the face on the same side and disturbance of sensation for pain, heat and cold over the other side of the body.

Sometimes large tumors of the thalamus extend downward and implicate the peduncle on one or both sides. In such instances the diagnosis is difficult until the third nucleus becomes involved and with the presence of the paralysis of upward associated ocular movement the diagnosis can be made.

Lesions of the Middle Cerebellar Peduncles.—Tumors in this area are rare. Such lesions usually either extend from the pons into the cerebellum by means of this peduncle or grow from the cerebellum into the pons. Hemorrhages or a thrombosis often give limited symptoms. One such case is now under our observation. This patient, a physician of 45 years, suddenly developed numbness on the entire left side of the body with a complete motor right fifth nerve palsy and a partial weakness of the right sixth nerve. He had besides limited cerebellar disturbances in the limbs of the involved side which were best brought out by the Bárány tests. In this instance the diagnosis was made by the presence of the fifth and sixth nerve palsy on the side of the lesion, the sensory symptoms on the opposite side due to the irritation of the median lemniscus and the slight cerebellar asynergy on the side of the lesion.

---

[2] Mills, Charles K.: Preliminary Note on a New Symptom Complex Due to Lesion of the Cerebellum and Cerebello-Rubro-Thalamic System, the Main Symptoms Being Ataxia of the Upper and Lower Extremities of One Side, and on the Other Side Deafness, Paralysis of Emotional Expression in the Face, and Loss of the Senses of Pain, Heat and Cold Over the Entire Half of the Body, Jour. Nerv. and Ment. Dis., February, 1912.

[3] Weisenburg, T. H.: Tumors of the Third Ventricle with the Establishment of a Symptom-Complex, Brain, 1910, xxxiii, 236.

The conclusion can be drawn that in lesions of the middle cerebellar peduncles the associated phenomena consist of the fifth or sixth nerve symptoms on the side of the lesion, with sensory and motor phenomena on the opposite side.

Lesions of the Inferior Cerebellar Peduncles.—Such tumors are very rare and we have never seen one *limited* to one or both of the inferior peduncles. We have, however, seen a number of tumors of the cerebellum in which there has been an extension of the growth into one or both peduncles. In such growths the associating phenomena, if the lesion extends into the medulla, should consist in implication of the vestibular tract, and disease of the ninth, tenth and twelfth cranial nerves.

Lesions of the Cerebellopontile Angle.—The diagnosis of tumors in this area as a rule is not difficult. We have encountered cases, however, in which such diagnosis had been made, only to find that this angle was invaded secondarily by tumors growing from the cerebellum and more rarely from the pons. The differential diagnosis is important from the surgical standpoint, for it is readily seen that tumors growing *from* the pons or cerebellum offer little hope for surgical removal.

Tumors growing in this angle are usually fibromatous and more rarely fibrosarcoma. We have encountered a number of cysts, but these are generally parts of gliomatous tumors growing from the cerebellum. Most tumors grow from the eighth, and more rarely from the seventh, fifth, or sixth cranial nerves, respectively. The first symptoms are usually referred to the cranial nerve from which the tumor grows and in the course of time the seventh, sixth and fifth nerves become implicated. Of course, the symptoms depend on the size of the growth. In small tumors no pressure is exerted on either the pons or cerebellum. In a well-developed case, besides the cranial nerve symptoms, because of the pressure on the pons, there are motor symptoms on the opposite side and more rarely sensory phenomena.

Because of the pressure on the anterior part of the cerebellum, both the superior and inferior surfaces are involved, this causing cerebellar asynergy of the limbs on the same side. In cases in which the angle is invaded secondarily from the cerebellum or from the pons, the cerebellar symptoms are always much more marked, and it is because we have not been sufficiently careful in the differentiation of the cerebellar phenomena that errors in diagnosis have arisen.

We wish to emphasize here that in the usual tumor growing from the cerebellopontile angle the cerebellar symptoms *are not very marked* and that unless the tumor is very great the asynergy will be limited only to the arm and leg on the side of the growth, and that if there is in addition to the cranial nerve symptoms cerebellar asynergy in the trunk and limbs on both sides, it is probable that the tumor grows either from the cerebellum or more rarely from the pons.

Of course, if the progress of the symptoms is carefully noted, in the latter type of case the cerebellar phenomena should occur first and the cranial nerve symptoms last. But unfortunately we are not always permitted a clear-cut history, and it is because of this that we desire to emphasize this important point in differential diagnoses.

2030 Chestnut Street, Philadelphia—Woodcroft Hospital, Pueblo.

GALVANOMETRIC STUDIES OF THE CEREBELLAR FUNCTION *

I. LEON MEYERS, M.D.
Associate in Neurology, Rush Medical College
CHICAGO

The object of this study has been to ascertain, if possible, the mechanism of the cerebellar function, as deduced from the phenomena consequent to its lesions. It will be necessary, therefore to formulate at the outset a clear conception as to which of such phenomena are essentially cerebellar in origin. The cerebellum is adjacent to so many important structures and forms such intimate connections with the vestibular system and its oculomotor tracts that many of its lesions, experimental, as well as clinical, but especially the latter, very frequently implicate these other structures, producing their corresponding symptoms. On reviewing the literature we find, therefore, that a number of symptoms have from time to time been ascribed to this organ which have not had their genesis in it at all.

THE CEREBELLUM AND SENSORIUM

Lesions of the cerebellum do not produce disturbances of sensibility, and if these are present, they are invariably due to the involvement of the sensory tracts or nerves found in its vicinity. This is attested by such a great number of observations that it may well be considered an indisputable fact.

What was said with regard to general sensibility applies with equal force to that type of sensation which is implied by the general term of the "muscular sense." As is well known, this type of sensation comprises all those sensory reactions which, originating in the motor organs and their accessories (tendons, joints, etc.), provide us with information as to their state of tension, their direction in active and passive movements, and incidentally aid us in the appreciation of our posture in space. The cerebellum has been thought to be the center of the muscle sense by such noted observers as Lussana,[11] Hitzig, Munk[12] and of late Lewandowsky, and the spinocerebellar tracts have been identified by them as the carriers of the so-called proprioceptive stimuli. It is an undeniable fact, however, that pure cerebellar lesions do not give rise to loss or impairment of the muscle sense and, if this is present, there is invariably found an associated lesion of the posterior columns or their nuclei.[13] Patients with cerebellar disease have complete orientation toward the surrounding world, are fully conscious of all changes in posture during active and passive movements and present no Romberg sign (swaying on being deprived of the aid of vision). As pointed out by Luciani, the dog deprived of a lateral lobe of the cerebellum even anticipates the disturbances that will ensue on walking or prehension of food, and to obviate a fall seeks out some support for the side of the lesion.

THE CEREBELLUM AND MOTILITY

The phenomena consequent to cerebellar lesions belongs to the motor sphere and not to the sensory. This is almost universally conceded now by both physiologists and clinicians. The disturbances manifest themselves, however, in such a large variety of phenomena, owing chiefly to concomitant lesions of other structures, that their interpretation has for a long time been exceedingly difficult. Of late, however, thanks to our increasing knowledge of the anatomy and physiology of the cerebellum as well as of its adjacent structures, this difficulty has been largely removed, and we are able to dissociate the true cerebellar phenomena from the others.

FORCED MOVEMENTS, NYSTAGMUS, ETC.

It is pretty definitely established that such phenomena as forced movements, the circus movements and rolling movements in animals and the so-called imperative movements in man, are not cerebellar in origin. And the same is true of the nystagmus, the conjugate deviation of the eyes and the characteristic attitude of the head so frequently observed after unilateral ablation of the cerebellum in animals and occasionally in cerebellar disease of man.

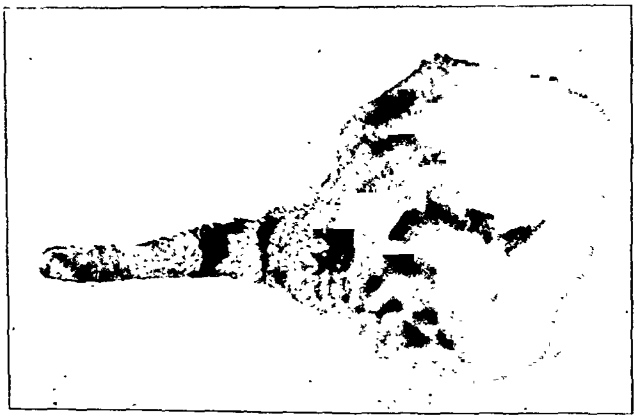

Fig. 1.—Cat after removal of left motor area of the cerebrum and right lateral lobe of the cerebellum. From photograph taken fifteen days after the first operation and fifteen days after the second. Note marked extension of right forelimb on prolonged standing. The extension is not due to a spasmodic condition of the forelimb, as it takes place gradually and is brought about by the weight of the body forcing the paretic limb out.

These phenomena are essentially vestibular in origin, being due to a lesion of the vestibular complex itself or its oculomotor tracts. Muskens,[14] who made an extensive study of these phenomena in their relation to the pathologic findings at necropsy, found that they are associated with lesions in the paracerebellar nuclei, the vestibulomesencephalic tracts in the posterior longitudinal bundle and the descending vestibulospinal tracts. They are, at any rate, not cerebellar symptoms. The whole lateral lobe of the cerebellum may be removed without producing the slightest indication of these phenomena. I have personally performed such operations in about twenty-five animals (dogs and cats) and can say without hesitation that forced movements as well as nystagmus are not cerebellar in origin. I have seen no instance of rolling movements or a tendency to it in pure cerebellar lesions. They were, however, extremely vehement and almost uncontrollable whenever there was an associated lesion of the vestibular system. These movements in my cases were invariably toward the side of the lesion in accordance with the results of Schiff,[15] Ferrier and Turner,[16] André-Thomas, and Muskens[14] in lesions of the cerebellum, and those of Bechterew[17] and Breuer[18] after section of the eighth nerve.

THE PHENOMENA OF CEREBELLAR LESIONS

The phenomena that are purely cerebellar in genesis are two, the ataxia and the tremor. I am using the term "ataxia" in its general sense to denote irregularity or perversion of muscular action without reference to its nature, and in contradistinction to loss of movement such as is found in paralysis. Personally I have never been convinced as to the existence of hypotonia in cerebellar lesions, a symptom on which Luciani laid so much stress. In my experience, which is in accord with that of Ferrier, it is very inconstant. I have noted it only in very extensive lesions, in lesions which have involved also the vermis and its nuclei. The nucleus tecti, as established by the morphologic studies of Weidenreich[19] and others, may be looked on as a part of the paracerebellar nuclei, which, from their rôle in the production of decerebrate rigidity (Thiele[20]) are known to dominate the tonicity of the body musculature. The presence of hypotonia in such severe lesions of the cerebellum is thus easily explained without attributing it to a disturbance of the chief function of the organ. The ataxia and tremor, on the other hand, are constant and marked, and found in lesions limited to the lateral lobes and in the absence of any involvements of the vestibular complex. And it is to interpret these phenomena that our efforts should be directed in attempting to decipher the complex and mysterious problem of the mechanism of the cerebellar function.

THE INTERPRETATION OF THESE PHENOMENA

There have been numerous theories advanced in explanation of these phenomena. Flourens, Vulpian,[23] Renzi and Dickinson interpreted them as disturbances of coordination, attributing to the cerebellum that function which, according to Foerster's definition of coordination, enables the organism by means of its muscles to produce external effects which fulfil a definite purpose or a set task, accomplishing these effects with the smallest possible waste of energy. Bouillaud,[24] Ferrier and Thomas thought the cerebellum to be an organ for the maintenance of body equilibrium and endeavored to explain the phenomena of the lesions on that hypothesis. Babinski,[25] basing his opinion on clinical studies, proposed the theory of asynergia of movements, according to which it is essentially lost in cerebellar lesions in the harmonious association of simple movements necessary for the execution of a complicated movement and he endeavored to prove it by certain clinical tests. Babinski admitted, however, that in addition to asynergia there is also a dysmetria which is the cause of the excessive and ill-proportioned movements in cerebellar lesions. As to the asynergy, it is of course clear that it is merely a broad, general term for incoordination, and this conception of the nature of the disturbances aids us but little in understanding the mechanism of their production.

According to Holmes and Stewart the cerebellar phenomena are the result of defective cooperation of muscles and their antagonists. The cerebellum, according to this view, effects relaxation of the extensors while the flexors are in a state of contraction, and relaxation of the flexors while extension is in progress, the same being applied to the abductors and adductors.

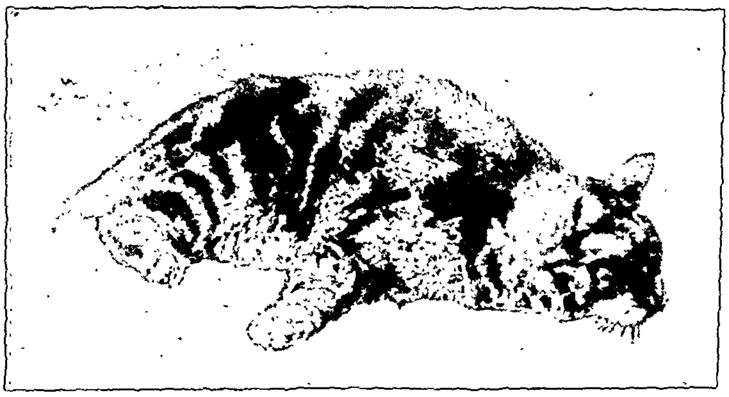

Fig. 2.—Same cat as shown in Figure 1. In standing posture for two or three minutes. Considerable abduction of both limbs on right, paretic side.

OBJECTIONS TO THE FOREGOING VIEWS

There are two points in common to all these theories: First, they all ascribe to the cerebellum a function which is totally distinct from that possessed by any other part of the nervous system, a function that is closely allied with motor activity but still different from it in a vague, indefinite way. Secondly, the function of the cerebellum, according to any of these theories, cannot be expressed in the terms of a single neuron effect. It is of course evident that coordination of movement, synergy of movement, etc., an effect which manifests itself simultaneously in a large group of muscles, widely isolated from each other and differing in their mode of action, cannot be the expression of an individual neuron. It must be the resultant effect of a large number of neurons all functioning at the same time. This conception of function is, however, entirely unnecessary for our understanding of the activity of any other nerve structure, in which case each unit, whether motor or sensory, may exhibit its individual function independently of the other neurons and produce a corresponding effect.

Notable among these was Risien Russell, who maintained that unilateral ablation of the cerebellum was in his experiments followed by genuine paralysis on the side of the lesion, entirely identical with that following ablation of the motor area of the cortex. This is, however, denied by the majority of observers. There was no paralysis in the animals operated on by Bouillaud,[24] Dalton,[26] Longet,[27] Munk and Ferrier and Turner.[16] Personally, I am convinced that pure cerebellar lesions do not give rise to paralysis. One has only to compare the gait of an animal after destruction of the motor area of the cerebrum with that which follows unilateral ablation of the cerebellum to be impressed by the marked dissimilarity between these two conditions. In the former instance, the limbs on the side opposite to the lesion are distinctly paretic; they are unable to support the animal on that side; they bend under it and are frequently placed with the dorsal surface to the ground. In the latter condition, on the other hand, the limbs on the side of the lesion are generally in full extension; they are never placed with the dorsal surface to the ground, but are usually thrown violently forward or outward, and the frequent falls are therefore to be attributed to the ill-proportioned activity of the muscles rather than to loss of their activity.

GOWERS' HYPOTHESIS

Gowers,[33] as far as I can ascertain, was the only one to maintain, on purely theoretical grounds, that the cerebellum has no downward effect whatever, that it exhibits its influence on the cerebrum exclusively, this influence being inhibitory in character, and that cerebellar coordination is nothing else than coordination of the activity of the rolandic cortex. His arguments in support of this theory were as follows: The cerebellum is connected with the periphery by means of afferent or upbearing tracts exclusively. The only efferent or outgoing tracts known to come from it pass by way of the superior cerebellar peduncle to the opposite hemisphere of the cerebrum, and it is inconceivable that an organ having no outgoing tracts to the periphery could exert a direct motor effect on it. Continuing he said:

> The will may alter any muscular contractions by which the upright posture is maintained, and yet without thus being deranged for an instance, and it is difficult to understand how this is possible if the two motor effects, the cerebral and cerebellar, take place apart, and equally difficult if we assume that they only come together in the subordinate centers in the spinal cord.

He therefore concluded that the cerebellum exhibits its function on the motor cortex of the opposite hemisphere of the cerebrum by way of its efferent tracts passing along the superior cerebellar peduncles, and that this function is inhibitory in character, in view of the fact that evidence at hand tends to show that when one set of cells exerts an influence on another set, this is in the nature of control, as witness the influence of the cortical motor cells on the spinal cells in the anterior horns. We must distinguish, said Gowers, between the continuous action of nerve cells, which by its nature needs control and restraint, and occasional action, which requires stimulation, and conceived as excitation.

According to this conception, the phenomena consequent on cerebellar lesions are only indirectly cerebellar; they are primarily cerebral effects, and, like the increased reflexes and spasticity after lesions of the upper motor nervous system, are due to removal of inhibition on the nerve cells directly concerned in their production.

[33] Gowers, W. R., Lancet, London, 1890, i, 955.

It is evident from the foregoing that, according to Luciani, Hughlings Jackson and others, the disturbances of motility in cerebellar lesions are the expression of diminished or lost functional activity on the side of the lesion; according to Gowers, on the other hand, they are the result of exaltation of such activity.

It occurred to me that the problem could be taken out from the realm of pure speculation and solved by means of the galvanometer.

SOLVING THE PROBLEM GALVANOMETRICALLY

It is well known that living tissue in a state of activity exhibits four kinds of phenomena, mechanical, chemical, thermal and electric. Of all these the electric phenomena are the most faithful; they are to be observed, especially so in the case of nerve tissue, when none of the others can be elicited.[34] Among the electric phenomena is the state of negativity which excited tissue assumes with relation to the quiescent part thereof. On connecting two such parts with a galvanometer, with the circuit closed, a current is seen to pass through it, as evidenced by the deflection of the needle, from the quiescent to the active part. The former is therefore in its external or galvanometric relations positive to the latter. In completing the circuit and passing through the tissue the current of course passes in the opposite direction, from the active to the resting part. Active tissue, in other words, behaves electrically toward quiescent tissue as the zinc element of a voltaic couple behaves toward the copper element — it is with regard to the outer or galvanometric circuit, negative to the latter. While this electric phenomenon, the so-called action current, is generally studied by means of the negative variation, or the diminution of the preexisting current of injury which accompanies the excitation of the tissue, the latter, says Hermann,[35] is only a special case of a more general phenomenon, which is, that active tissue is, properly speaking, invariably negative (or "zincative," according to Waller) to resting tissue quite independently of previous preexisting currents. The action current is also entirely independent of the agency which provoked the activity in the tissue. The stimulus may be chemical, mechanical, thermal or electric; it may be direct or indirect. Gotch and Horsley[36] have thus demonstrated that the action current manifests itself in a peripheral nerve, not only on direct excitation of the nerve, but also on stimulation of the contralateral and functionally related motor area of the cerebrum.

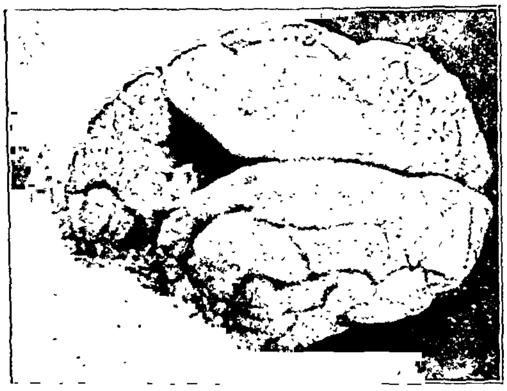

Fig. 3.—Brain of cat shown in Figures 1 and 2.

That natural nervous activity is, like that resulting from artificial stimulation, accompanied by the development of a negative state, has been demonstrated by A. Beck,[37] Alcock and Seemann,[38] Einthoven[39] and others. Beck removed the brain, spinal cord and sciatic nerves of a frog *en bloc* and placed the preparation on a glass plate. He then applied nonpolarizable electrodes to various parts of the nervous system and connected them with a galvanometer. He found that there was uniformly an electrical difference of such a nature that the proximal, more active parts of the nervous system were negative to the distal parts. Alcock and Seemann and Einthoven studied the impulses which traverse the vagus during natural respiration and found that a state of negativity invariably passes along the nerve with each inspiratory excursion. The latter also observed minor effects which accompanied the large waves of the inspiratory acts and corresponded with rhythmic contractions of the heart. A natural corollary to this should be that, if active tissue on one side of the body were connected by means of a galvanometer with the corresponding quiescent tissue on the other side, the former would be negative to the latter. That this is so for direct stimulation has been demonstrated by Hermann and Luchsinger, Waller and others in their study of skin currents. On connecting the pads of the hind paws of a cat with the galvanometer and stimulating the sciatic nerve for one of these, the corresponding pad has been found to be negative to the other. In this case the current in its internal circuit has to traverse, of course, from one side of the body to the other. That this holds true for indirect stimulation of tissue I have proved to my satisfaction by the following experiment:

With the cat under ether anesthesia, by means of a tracheal cannula I carefully exposed and isolated both sciatics. After drying all hemorrhage, I freed the nerves from contact with any of the surrounding tissue — which of course had been injured during the operation — and placed them on the boots of nonpolarizable boot electrodes, which had been soaked in Ringer's solution for the preceding twenty-four hours. I connected these with a galvanometer with a contact key in the circuit. The galvanometer employed during this and the other experiments to be described was of the Thomson type and manufactured by Elliot Brothers, London. It had a resistance of 20.74 ohms and its sensitiveness was such that at 37.5 cm. of scale distance 1 cm. deflection, registered 0.0000154 ampere of current, so that its constant (K) was 0.00155 ampere $\left(K = \frac{2I \times D}{d}\right)$.

While an experiment was in progress the nerves were kept moist with cotton sponges soaked in normal salt solution at a temperature of 38 C., which were removed during each observation so as to prevent any possible short-circuiting. The sponges were always applied to both nerves at the same time in order to avoid any possible differences of surface temperature.

with the smallest possible waste of energy. Bouillaud,[24] Ferrier and Thomas thought the cerebellum to be an organ for the maintenance of body equilibrium and endeavored to explain the phenomena of the lesions on that hypothesis. Babinski,[25] basing his opinion on clinical studies, proposed the theory of asynergia of movements, according to which it is essentially lost in cerebellar lesions in the harmonious association of simple movements necessary for the execution of a complicated movement and he endeavored to prove it by certain clinical tests. Babinski admitted, however, that in addition to asynergia there is also a dysmetria which is the cause of the excessive and ill-proportioned movements in cerebellar lesions. As to the asynergy, it is of course clear that it is merely a broad, general term for incoordination, and this conception of the nature of the disturbances aids us but little in understanding the mechanism of their production.

According to Holmes and Stewart the cerebellar phenomena are the result of defective cooperation of muscles and their antagonists. The cerebellum, according to this view, effects relaxation of the extensors while the flexors are in a state of contraction, and relaxation of the flexors while extension is in progress, the same being applied to the abductors and adductors.

OBJECTIONS TO THE FOREGOING VIEWS

There are two points in common to all these theories: First, they all ascribe to the cerebellum a function which is totally distinct from that possessed by any other part of the nervous system, a function that is closely allied with motor activity but still different from it in a vague, indefinite way. Secondly, the function of the cerebellum, according to any of these theories, cannot be expressed in the terms of a single neuron effect. It is of course evident that coordination of movement, synergy of movement, etc., an effect which manifests itself simultaneously in a large group of muscles, widely isolated from each other and differing in their mode of action, cannot be the expression of an individual neuron. It must be the resultant effect of a large number of neurons all functioning at the same time. This conception of function is, however, entirely unnecessary for our understanding of the activity of any other nerve structure, in which case each unit, whether motor or sensory, may exhibit its individual function independently of the other neurons and produce a corresponding effect.

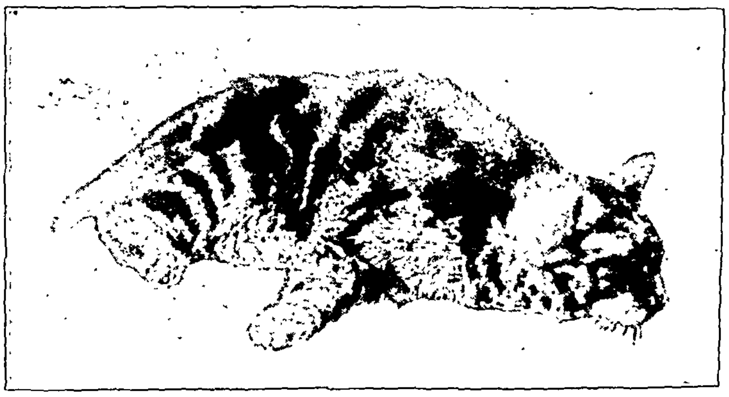

Fig. 2.—Same cat as shown in Figure 1. In standing posture for two or three minutes. Considerable abduction of both limbs on right, paretic side.

Notable among these was Risien Russell, who maintained that unilateral ablation of the cerebellum was in his experiments followed by genuine paralysis on the side of the lesion, entirely identical with that following ablation of the motor area of the cortex. This is, however, denied by the majority of observers. There was no paralysis in the animals operated on by Bouillaud,[24] Dalton,[26] Longet,[27] Munk and Ferrier and Turner.[16] Personally, I am convinced that pure cerebellar lesions do not give rise to paralysis. One has only to compare the gait of an animal after destruction of the motor area of the cerebrum with that which follows unilateral ablation of the cerebellum to be impressed by the marked dissimilarity between these two conditions. In the former instance, the limbs on the side opposite to the lesion are distinctly paretic; they are unable to support the animal on that side; they bend under it and are frequently placed with the dorsal surface to the ground. In the latter condition, on the other hand, the limbs on the side of the lesion are generally in full extension; they are never placed with the dorsal surface to the ground, but are usually thrown violently forward or outward, and the frequent falls are therefore to be attributed to the ill-proportioned activity of the muscles rather than to loss of their activity.

GOWERS' HYPOTHESIS

Gowers,[33] as far as I can ascertain, was the only one to maintain, on purely theoretical grounds, that the cerebellum has no downward effect whatever, that it exhibits its influence on the cerebrum exclusively, this influence being inhibitory in character, and that cerebellar coordination is nothing else than coordination of the activity of the rolandic cortex. His arguments in support of this theory were as follows: The cerebellum is connected with the periphery by means of afferent or upbearing tracts exclusively. The only efferent or outgoing tracts known to come from it pass by way of the superior cerebellar peduncle to the opposite hemisphere of the cerebrum, and it is inconceivable that an organ having no outgoing tracts to the periphery could exert a direct motor effect on it. Continuing he said:

> The will may alter any muscular contractions by which the upright posture is maintained, and yet without thus being deranged for an instance, and it is difficult to understand how this is possible if the two motor effects, the cerebral and cerebellar, take place apart, and equally difficult if we assume that they only come together in the subordinate centers in the spinal cord.

He therefore concluded that the cerebellum exhibits its function on the motor cortex of the opposite hemisphere of the cerebrum by way of its efferent tracts passing along the superior cerebellar peduncles, and that this function is inhibitory in character, in view of the fact that evidence at hand tends to show that when one set of cells exerts an influence on another set, this is in the nature of control, as witness the influence of the cortical motor cells on the spinal cells in the anterior horns. We must distinguish, said Gowers, between the continuous action of nerve cells, which by its nature needs control and restraint, and occasional action, which requires stimulation, and conceived as excitation.

According to this conception, the phenomena consequent on cerebellar lesions are only indirectly cerebellar; they are primarily cerebral effects, and, like the

[33] Gowers, W. R., Lancet, London, 1890, i, 955.

It may be assumed, however, that the hyperactivity originates in the paracerebellar nuclei, especially Deiters' nucleus. These nuclei, like the vagal cells in the medulla are known to possess automatic activity, as proved by the decerebrate rigidity following transection of the mesencephalon. Thiele[20] in an extensive study of this rigidity has shown that it originates in these nuclei and that the cerebellum exerts an inhibitory effect on them. Stimulation of the cerebellum produces immediate relaxation of such rigidity, as demonstrated by Sherrington[40] as well as Lowenthal and Horsley.[41]

It may also be assumed that the hyperactivity has its origin in the midbrain or the basal ganglia and that the inhibitory effect of the cerebellum is exerted on these structures. While later investigations tend to deny these structures a motor function, there is evidence that they participate in the production of movement to some extent.

And, finally, it may be supposed, as Gowers theoretically assumed, that there is hyperactivity on the side of the cerebellar lesion which originates in the contralateral motor area of the cerebellum.

To determine this point, I carried out the following experiments: In one cat I removed a very large portion of the right hemisphere of the cerebrum but left the motor area intact. In three others I removed only the motor area. The first cat showed no paralysis on the *opposite side*; the three others showed it to a very marked degree. Ten to fifteen days after the cerebral operation I removed in these cats the lateral lobe of the cerebellum, contralaterally to the previous lesions (of the three last, two had the right motor area of the cerebrum and the left lateral lobe of the cerebellum removed, and one the left motor area of the cerebrum and the right lateral lobe of the cerebellum) and kept them under observation for fifteen days more. The first cat showed ataxia on the side of the cerebellar lesion, but, as before, no paralysis. The three last, on the other hand, were markedly paralyzed on that side. They showed no ataxia, but did show considerable tremor, involving head, trunk and paretic limbs. The presence of the tremor in these cases, after destruction of motor area, would indicate that this symptom is not entirely cerebral in origin, a supposition advanced, on theoretical grounds, by Gordon Holmes[42] and Kinnier Wilson.[43]

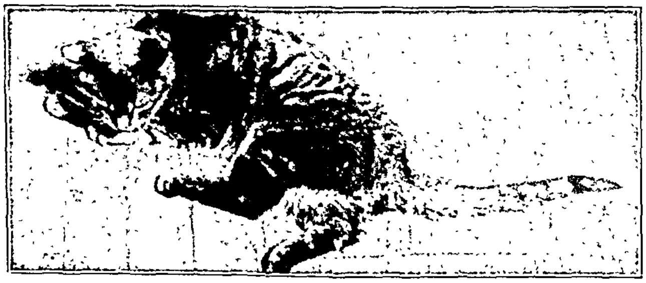

Fig. 5.—Cat shown in Figure 4, after remaining in that posture for two to three minutes. Animal falls over to the right, owing to hyperactivity of the muscles supporting the body on that side (see text).

Galvanometrically these cats gave the following results: The first one, with the motor area intact, although with a large portion of the cerebrum removed, showed a persistent and invariable negativity on the side of the cerebellar lesion, identically the same as in those animals in which a cerebellar lesion only had been produced. The three others, on the other hand, with a lateral lobe of the cerebellum removed and the additional extirpation of the contralateral motor area of the cerebrum, gave no galvanometric deflection whatever. I kept up my observations in these animals for nearly three hours and not once was there a deviation from this rule. Fearing that there was no deflection obtained in the last animals because of a possible fault in the circuit, I cut the sciatic nerve and applied the nonpolarizable electrodes to it in such a manner that one was in contact with the longitudinal surface and the other with the cross section. A current of injury was promptly obtained, showing that there was no such fault there.

The results obtained thus tend to show that the hyperactivity on the side of the cerebellar lesion, as *shown by its being electrically negative ("zincative")* to the other side, originates in the contralateral motor area of the cerebrum; that following unilateral ablation of the cerebellum the contralateral motor area of the cerebrum becomes hyperexcitable, has been found by *Risien Russell*[9] *and confirmed in part by* Luciani.[4] Their results were denied by Bianchi.[44] Cerebellar incoordination is, therefore, in accord with Gowers' hypothesis, only indirectly cerebellar; it is primarily a cerebral effect, an expression of its hyperactivity consequent to the removal of inhibition or control by the opposite half of the cerebellum. The hyperactivity manifests itself in all the movements in that they are excessive, forcible, unchecked and go beyond the mark. In walking the animal throws its foot violently forward; in seizing food its paw goes beyond it, etc. Clinically, as Babinski pointed out, cerebellar patients, in performing the finger-to-nose test, are unable to stop the movement when the point aimed at is reached, and the finger goes beyond it, violently striking the jaw. Similarly, when tracing on a sheet of paper a line which should be stopped at a certain point, the pen goes way beyond this limit. The symptom of adiadokocinesis is therefore best explained by assuming it to be a result of the dysmetria and excess of each component movement, such as pronation and supination, a view suggested by Thomas, rather than that it is due to a delay in the excitomotor activity, as thought by Babinski, the discoverer of this phenomenon.

This conception of the cerebellar function is also in accord with certain well-established anatomic and clinical facts. The cerebellum develops embryologically from the rhomboidal lip of His, along the sensory tracts, as an accessory to them. Anatomically it is too, as Edinger, Sherrington, Gowers and others pointed out, a sensory organ. The effects of its lesions are, however, motor in character. This contradiction between its anatomy and physiology does not exist if we assume the motor phenomena to be cerebral in origin, and the function of the cerebellum to be that of control and restraint, such, to use a crude simile, as that of the vagus, which is also a sensory structure.[45]

44. Bianchi, quoted by Sherrington: Schäfer's Text-Book, ii, 904.

45. It was held by Waller, Schiff and others that the inhibitory fibers of the vagus originate in the nucleus of the spinal accessory. This seems to be disproved, however, by later investigations. (Luciani: Human Physiology, i, Chapter 9.)

Another mystery cleared up by this conception of the cerebellar function is the path by which the cerebellar effects exhibit themselves on the periphery. As is well known, in view of the fact that the cerebellum has no descending tracts to the spinal cord, and also that the effects of its lesions manifest themselves homolaterally and not contralaterally, as is the case in lesions in all other motor and sensory tracts, it was found necessary to conceive an unusual and circuitous course for the transmission of its impulses. It is assumed that, originating in the deep nuclei of the cerebellum, the impulses first ascend by way of the cerebellomesencephalic tracts to the red nucleus of the opposite side and there are relayed, and finally descend by way of Monakow's bundle, or rubrospinal tract, crossing again to reach the spinal on the side whence they first started. This course, besides being different from that of all other motor and sensory structures which, as a rule, cross to the opposite side to exhibit their effect there, and, if homolateral in function, as the direct pyramidal tract or the vestibulospinal tract, go by direct route to the same side, is also untenable in the light of certain anatomic facts. The cerebellum attains its largest development in man, whereas the rubrospinal tract, by which its impulses are supposed to be carried, has been demonstrated only in animals and is in man at best only rudimentary.

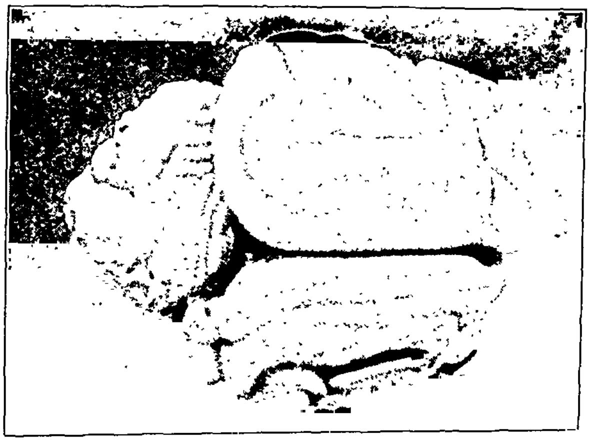

Fig. 6.—Brain of cat shown in Figures 4 and 5.

According to our conception, however, each half of the cerebellum exhibits its function on the opposite hemisphere of the cerebrum, its tracts crossing to the other side like those of all other sensory tracts. Its indirect effects, in the form of regulated and well-proportioned movements, manifest themselves on its own side, as, originating in the motor cortex of that hemisphere of the cerebrum, the motor impulses, passing by way of the pyramidal tracts cross to the opposite side before reaching the "final common path" in the spinal cord.

Finally, there is a good deal of evidence that there is a structural linkage between the cerebral hemisphere of one side and the cerebellar of the other side, and that the cerebellum is subservient to the cerebrum. It has been observed clinically in cases of congenital or acquired atrophy of the cerebrum, and experimentally after destruction of the motor cortex, especially if the optic thalamus was involved in the lesion, that there was simultaneously in the congenital lesions or after some time in the acquired variety, an atrophy or degeneration of the opposite lateral lobe of the cerebellum. These cases are described under the name of crossed hemiatrophy.

With reference to the tremor it appears to be largely dependent on an interaction between the cerebellum and the midbrain structures. I am engaged in some experiments with reference to these points at present and hope to communicate the results at some time in the future.

To sum up, the cerebellum is a complex structure having no direct effect on the periphery, but acting primarily on the motor cortex, the paracerebellar nuclei, and probably also the basal ganglia and ruber. Its primary effects are those of inhibiting, controlling and regulating the activity of these latter structures. Its ultimate effects are appropriate and rhythmic muscular action.

5 South Wabash Avenue.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. GREY, WEISENBERG AND WORK, AND MEYERS

Dr. W. F. Schaller, San Francisco: Dr. Work brought out the relationship between certain symptoms and definite localization of lesions. Certainly this is progress in the right direction. It is not a question only of posterior fossa disease characterized by a syndrome, it is a question of exact anatomic localization. The only way we shall make an advance in this work is by correlating the symptomatology and pathology; by studying our specimens in macroscopic and microscopic serial sections.

Dr. Meyers does not believe that nystagmus is primarily an expression of disturbed cerebellar function. I am inclined to favor this view, and regard vestibular nystagmus as a reflex and as the motor expression of a stimulus somewhere along the vestibulo-ocular path: labyrinth, vestibular nerve, Deiters' nucleus, posterior longitudinal bundle and oculomotor nuclei. This stimulus may be due to a focal lesion, or to pressure. Dr. Grey in his conclusions stated that in posterior fossa tumor without nystagmus he was inclined to believe that the tumor was intracerebellar; and that in cases of extracerebellar tumor he generally found nystagmus. May I ask Dr. Grey if the reason for this was not that in cases of extracerebellar tumor the intracranial pressure was increased and the nystagmus was due to disturbance of function by pressure? If there be a nystagmus following cerebellar lesions proper, I believe it is due to involvement of the vermis in relation to its efferent fibers to Deiters', i. e., cerebellovestibular tract (*Hacken Bundel, faisceau en crochet*) which forms an arm of the nystagmus reflex in that stimuli are received in this way from the muscles and joints and pass to the vermis before acting on Deiters' nucleus. To illustrate these views I wish briefly to mention three posterior fossa cases recently studied clinically and anatomically. In the first case there was no nystagmus, no intracranial pressure. The lesion was a vascular one, limited to the white matter of both cerebellar hemispheres and involving the dentate nucleus on one side. There was marked ataxia of the cerebellar type. The vestibulo-ocular reflex path was not involved; hence absence of nystagmus. The second case was that of a right sided cerebellopontine angle tumor in which the usual signs of intracranial pressure, vertigo, nausea, headache and choked disks were absent. The tumor had caused a considerable atrophy of the cerebellar hemisphere on the same side and also the pons, and by replacing these structures had not materially added to the contents of the posterior fossa; hence absence of intracranial pressure. Ataxia of cerebellar type was marked. A slight nystagmus more marked to the right was explained by direct involvement of the vestibulo-ocular reflex. The third case was a tumor in the fourth ventricle arising from the inferior tela. The marked nystagmus could be explained by direct pressure of the growth on Deiters' nucleus. Ataxia was absent.

Dr. A. L. Skoog, Kansas City: The subject of cerebellar tumor is always interesting, and might be broadened to include any of the lesions in the cerebellum. The subject of cerebellar function has received a great deal of attention in the last few years and many new facts have been presented. However, as indicated by Dr. Work, many of the statements are really theoretical, which perhaps makes the subject still more interesting. As stated by several of the speakers, it invites the possibility of error in diagnosis. It has been stated that glioma is the most frequent type of tumor found in the cerebellum. This is in accordance with my own view. The glioma is a type of tumor which always springs from glia tissue, but there are those gliomas which are more dense than others, those that have a tendency to be better outlined. The type, however, is the infiltrating one and at times they are rather difficult to differentiate from some simple degenerating conditions of the central nervous tissue. I have always been interested to know whether there is any difference in symptomatology, even though the tumor be located in the same place, between the soft and infiltrating and the more dense one. That might be a reason for the difference in symptomatology which was brought out in the discussion.

Dr. G. W. Robinson, Kansas City: Dr. Work speaks of the diagnosis of tumors in the posterior cranial fossa. I should like to ask Dr. Work to speak on the differentiation between these and those situated more anteriorly and giving cerebellar symptoms. I recall two or three patients with lesions (tumor or trauma) of the frontal lobe, chiefly of the middle frontal convolutions, the apraxic center, giving a contralateral cerebellar syndrome. Another condition I have observed recently has been a patient with chronic progressive cerebellar tremor, without ataxia or nystagmus. I should like some of the men who read these excellent papers to tell us, if possible, the location of the lesion giving this particular symptom. I have recently observed two patients who had shown no nystagmus. At necropsy one had a degeneration of the right cerebellar hemisphere resulting from an encephalitis (associated with typhoid fever). The other had a large cyst involving the right cerebellar hemisphere.

Dr. John S. Turner, Dallas, Texas: These cases of cerebellar disturbance are very interesting to all of us and I rise to report a case and to present a question and to ask some of the gentlemen in closing to touch on it. It is in reference to a case recently occurring in our part of the country which became almost a medicolegal case, but by having the records properly presented a damage suit was prevented. The case came under my observation with all the typical symptoms of cerebellar tumor—nystagmus and other eye symptoms. The patient was a girl of 18, being able to go about, but not seeing very well, and having headaches, vomiting, titubation, disturbed coordination and considerable emaciation running over a long period of time. After observing the symptoms and making a tentative diagnosis, I sent her to a physician to look over the eye conditions. He confirmed my diagnosis in so far as the eyes were concerned, using some atropin to further dilate the pupil. Immediately after the dilatation the patient became blind and has never seen since that moment. Her headaches ceased, she gained in weight and was physically much better, but was totally blind. A damage suit was threatened against the physician for making the patient blind, but the records showing that she was partially so, and the opinion that she would ultimately become blind anyway prevented the suit.

Dr. Cecil E. Reynolds, Los Angeles: Dr. Work laid stress on the paralysis of the sixth nerve in cerebellar lesions, and I think it is very important. I remember a case of Dr. Charles A. Ballance of London at the Great Ormond Street Hospital in 1905, in which there was weakness of the sixth nerve on the left side and a bulging of the occipital fossa on the right side. The optic neuritis was more advanced on the left side. Mr. Ballance operated on the side which bulged, but the tumor was eventually discovered on the same side as the sixth nerve paresis. In my experience the signs of intracranial pressure have been more intense in cerebellar lesions and more early than in cerebral lesions, and this fact in a measure militates against the value of sixth nerve paralysis as a localizing sign in cerebellar disease, because in general increase of intracranial pressure the sixth nerve is often first affected by reason of that general pressure.

I would like to ask some of the gentlemen who have spoken as to their experience of the value of skew-deviation as a localizing sign. Dr. Robinson mentioned a confusion of frontal lobe lesions with cerebellar lesions. I have seen several cases in which a frontal lobe lesion was mistaken for a cerebellar lesion, and it appears to me that in cerebellar lesions the head is more twisted, with the chin pointing to the shoulder of the affected side, whereas in frontal lobe lesions the eyes deviate to one side or the other without much tilting of the head. Also I have noticed that in addition to hebetude out of proportion to the pressure, there is usually a slow and deliberate Babinski's sign in frontal lobe lesions, more sluggish than that usually seen in lesions of the pyramidal tract.

Dr. George A. Moleen, Denver: Just one remark on what Dr. Work said with reference to the extension of tumors from the thalamus downward. Is it not the rule to find unilateral paralysis of the third nerve prior to the involvement of conjugate deviation, the center of which lies pretty close to the sixth center in the pons? From this we presume there is a communicating fiber to the third, and in these extending tumors it would seem fair to expect a unilateral lesion of the third before the affection or disturbance of conjugate deviation would occur.

Dr. Philip Work, Pueblo, Colo.: We found in working up our pathologic material on this subject that cases which we thought definitely cases or tumor of one or other peduncle proved to be cases in which the involvement had gone past the peduncle, and the diagnosis and localization of symptoms has been hindered by the fact that these cases are so far advanced before they come to section. I personally believe that the matter of function of the peduncles—and coincident with it the establishment of a definite symptomatology—can only be hoped for when we have seen a sufficient number of early cases come to section. This is predicated on a series of necropsies from coincident cases in which the brain lesion was discovered incidentally in routine examination. The differential diagnosis of cerebellar and frontal tumor has been mentioned by one gentleman, but is too big a subject, I feel, to take up here. I have in mind several cases in our own series in which that identical question came up. In two cases in which the clinical diagnosis was made of cerebellar trouble, section showed frontal trouble, with definite cerebellar symptoms. These cases are being worked up at the present time, and we hope to be able to report something of value when we get them correlated. The loss of sight spoken of in the medicolegal case would seem to me to be due to the advanced state of the optic condition. The fact that the other symptoms abated more or less I do not attempt to reconcile.

Dr. Ernest Grey, Boston: Dr. Schaller has referred to increased intracranial pressure as an important factor in the production of nystagmus. This is the view of Bárány and others, and in our earlier work we inclined to the same belief. Recent observations, however, have led us to seek another explanation. We found nystagmus present in a group of patients with subtentorial new growths, some of whom had greatly increased intracranial pressure, while others had practically normal pressure. We have had a similar series of patients with the same variations in the degree of intracranial tension; none showed any nystagmus.

Dr. I. Leon Meyers, Chicago: Something has been mentioned in regard to nystagmus. I can simply add what I said in my paper—in my experience true cerebellar *lesions* do not give rise to nystagmus unless there is additional involvement of the vestibular complex. Skew-deviation has been observed in a few experiments on dogs during the time of anesthesia, but was lost after the animal awakened. Frederick Batten in a paper published *in Brain* in 1903 determined that the position of the head is not diagnostic of cerebellar lesions. It appears that the position of the head is due to the loss of knowledge of special relationship and is vestibular in origin. In my judgment the cerebellum is purely an organ which exerts an influence on other nerve cells in the brain structures—not on the periphery; the control it exerts is chiefly in the motor sphere.

OPERATIVE TREATMENT OF BUNIONS BY THE MAYO METHOD*

MELVIN S. HENDERSON, M.D.
ROCHESTER, MINN.

DEFINITION

The bunion is a painful bursitis superimposed on a hallux valgus. The degree of hallux valgus is by no means a criterion of the severity of the bunion (Fig. 1). The Mayo operation for bunion is for the relief of the painful bursitis and not a cosmetic operation for doing away with the deformity of the hallux valgus, though incidentally the deformity is reduced. For many years the operation[1] about to be described has been used in the Mayo Clinic and has given such satisfactory results that I think it wise to further emphasize its usefulness.

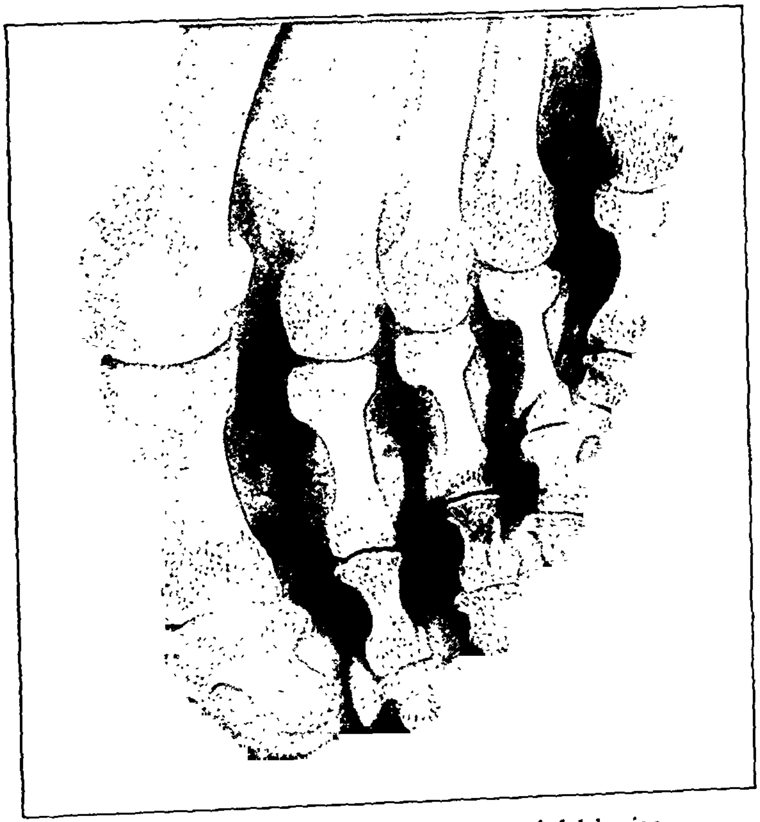

Fig. 1.—Moderate hallux valgus with painful bunion.

ANATOMY

Briefly we may consider the anatomic findings in this deformity. It is not seen in children who have never worn stiff shoes nor is it noted in individuals who have always gone barefoot. In these normal feet the great toe is in line with or turns slightly inward from the inner border of the foot. It has been stated that in the bunion foot the great toe is the longest, whereas the second toe should be of the same length or even a little longer. While this is not invariably true, still in this type of foot, that is, with the great toe the longest, the deformity is often present. In hallux valgus a line drawn through the anteroposterior axis of the great toe courses anteriorly outward at an angle of 30 degrees or more. The condition has generally been caused by wearing too short a shoe and this information is many times voluntarily given by the patient. The tendon of the extensor proprius hallucis becomes displaced outward and further increases the deformity. The pressure and irritation of the shoe causes more or less of a chafing action on the skin over the prominent inner aspect of the head of the first metatarsal bone. This irritation in many cases causes a distinct hypertrophy of the end of the bone and small bony exostoses occasionally form. Nature comes to the rescue with the formation of a bursa and we then have a bunion. It is only when this bursa becomes inflamed, mechanically or by infections, that tenderness results and surgery is indicated. Many cases go on to sepsis. When this occurs, operation should not be undertaken until the infection has completely subsided. Complete rest and alcohol dressings usually promptly clear up the infection. On top of the bursa may come a corn, adding further to the distress and inconvenience of the patient. Thus it may be stated that the symptoms depend not on the deformity but on the inflammatory changes in the bursal sac causing oftentimes continual discomfort and pain. The proximal phalanx of the first toe articulates often only against part of the head of the first metatarsal, the inner portion of the head impinging against the skin of the inner side of the foot. Often in patients in middle life or beyond, rarely in the young, there is an associated arthritis with deposits. These patients do not obtain the great relief accorded the nonarthritic cases. They should not on this account be denied the benefits of the operation, since formation of the new joint is a great relief.

All cases of hallux valgus do not cause inconvenience and many cases of moderate bunion had better not be interfered with surgically. Too often the cases are passed over lightly by the surgeon when the complaint is really a serious and disabling one to the patient and demands surgical interference. Bunion has long been looked on as a trifling condition, but to the individual with the pain it is anything but trifling.

---

OPERATIONS

Heuter[2] advised excision of the head of the first metatarsal bone for the relief of the condition. Hamilton[3] later reported eleven cases and his name is often mentioned in connection with the operation. Schede[4] advised excision of the bursa and removal of part of the head of the first metatarsal not in contact with the phalanx. Barker and Reverdin advised removal of the exostoses and of a wedge of the metatarsal just above the head. Various other operations have been suggested, such as removal of part of the proximal phalanx and part of the head of the metatarsal. It has been suggested that the head of the metatarsal bone be removed by an incision between the great and second toes, thus doing away with an incision on the inner side of the foot. The objection to an incision on the inner part of the foot we have found to be theoretic rather than real. By making a curved elliptical incision with the curve upward, it can be so arranged that the pressure of the shoe comes below and not on the line of incision. The operation has been performed in our clinic in 148 cases, nearly all of them double, with, on the whole, most gratifying results.

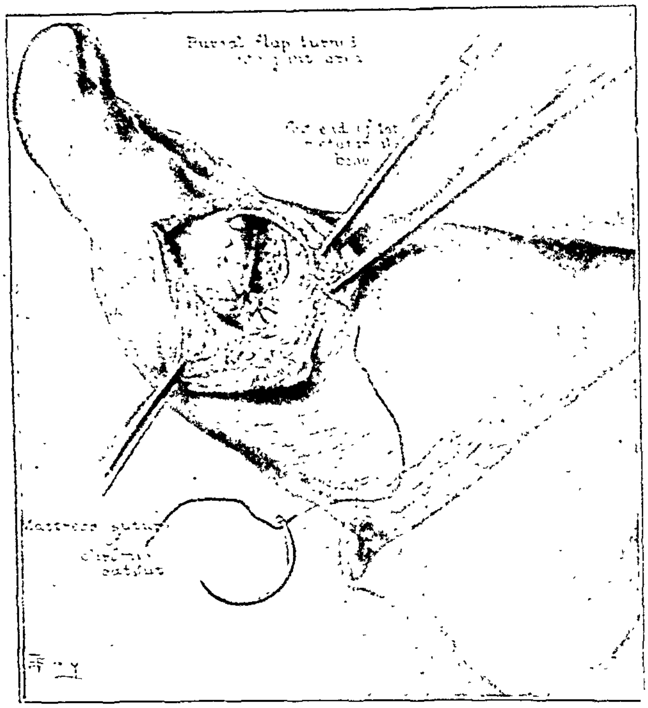

Fig. 3.—Head of bone removed. Bursal flap tucked in and approximated to periosteum of first metatarsal by two mattress sutures of chromic catgut.

Many patients have the condition associated with hammer toe, callosities on the bottom of the feet, etc., and unless it is carefully explained beforehand to the patients what they may expect from the operation, they may be disappointed that they are not relieved of all their foot trouble. However, in cases carefully selected, the results have been most excellent. Great care must be exercised in patients with flat feet to see that too much of the head is not excised. At the same time, enough must be excised to relieve the condition.

TECHNIC

The actual technic of the operation may be briefly stated: A semilunar incision with the curve upward is made at the metatarsal phalangeal joint of the great toe. The skin is dissected back, being careful not to puncture it. A flap including the bursa is then taken with its base attached to the proximal phalanx, having its convexity extending on to the head of the first metatarsal (Fig. 2a). The fat is then pushed back from around the head of the bone and a large bone-biter is introduced from without inward, aiming to take off most of the articulating surface of the head of the metatarsal bone, leaving sufficient of the enlarged end to serve as a weight-bearing portion (Fig. 3). This bone-biter is introduced at an angle of about 75 degrees so that the outer side of the metatarsal bone is a little longer than the inner side after the piece is removed (Fig. 4). With a rongeur bone-biter the prominence left on the inner side is smoothed down (Fig. 2b). The flap is then tucked in and the base of the flap sewed to the periosteum of the first metatarsal by two mattress sutures of chromic catgut (Fig. 3). This serves to straighten the toe and put it in its proper line. The skin is then closed with one or two sutures of silkworm gut and closer approximation is secured by interrupted horsehair sutures. A pad of gauze is inserted between the great and second toes to straighten the great toe (Fig. 5). A dressing soaked with alcohol is applied and carefully bandaged.

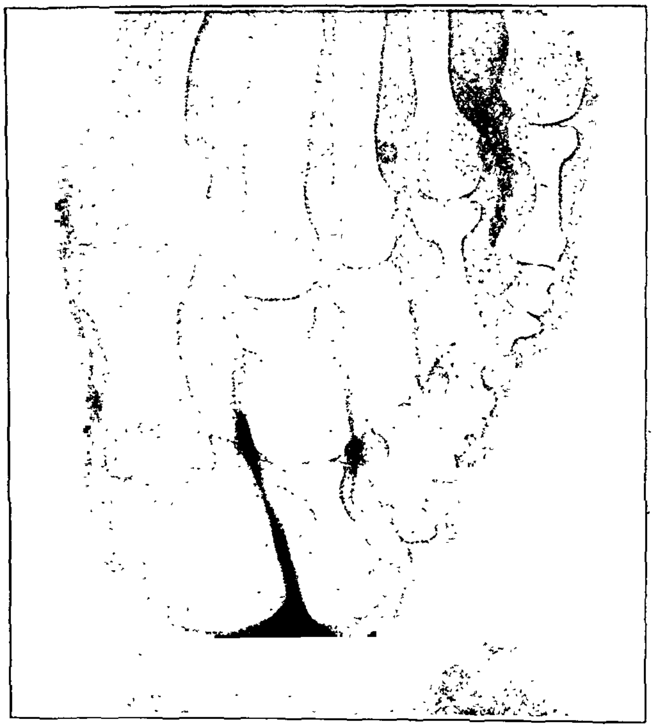

Fig. 4.—Greater part of metatarsal head removed, leaving sufficient of the expansion for weight-bearing.

AFTER-CARE

No splints are necessary. Pressure of the bed clothes is removed by the use of half barrel-hoops. Twice daily the bandage is opened enough at the end of the great toe to allow pouring in of alcohol, thus soaking the dressing and adding greatly to the comfort of the patient. Stitches are removed in a week, weight-bearing permitted in ten days and the patient encouraged to use the feet as soon as possible. A small pad

of gauze or cotton is to be worn between the first and second toes for a few weeks. The wearing of shoes with a proper straight inner side is insisted on. All patients will not follow this advice, but by carefully explaining why it is to be desired, the responsibility is then placed on them.

ABSTRACT OF DISCUSSION

Dr. E. W. Ryerson, Chicago: It is a rather difficult thing for me tactfully to say what I think about the Mayo operation, because I do not think it should often be done, unless it is impossible to bring the end of the first metatarsal bone and the phalanges of the toe into a straight line without undue force. It is undoubtedly true that a great many people have the wrong view of the Mayo operation. I have myself operated under the idea that it consisted in removing the entire head of the first metatarsal bone. That should never be done. It disturbs the balance of the foot so markedly, that people who have had the entire end of the first metatarsal removed are always more or less incapacitated. I have seen some thirty patients, about twenty of whom were operated on by me, and the others were operated on by other men, all of whom have had trouble after the Mayo operation. It is true that the bunion undoubtedly was cured, but they had a painful static disturbance of the foot and a severe type of flatfoot in all of these cases. Now what should be done? In many cases there is no bursa whatever, and in many other cases the bursa is small. There can be a much irritated skin without a bursa, and with the presence of a rather large—not always enlarged—metatarsal head, the divergence of the big toe outward, of course, allows the pressure of the shoe to come against the end of the metatarsal. The thing to do—and I have done it frequently with satisfaction—is to make exactly the same kind of an incision that Dr. Henderson and Dr. Mayo use; to push the toe down where it will be out of the way; to take a sharp chisel and start it at the front of the inner side of the metatarsal bone which is just where the edge of the phalanx comes, and cut backward, chiseling off the projecting portion of the bone. We can remove a piece an inch long, or even more, if necessary, down along the shaft of the bone, the portion of which is making the trouble, and it is extremely important to shave down the shaft of the bone just as carefully as one possibly can, so as to leave no little spicules of bone sticking out and no little shreds of periosteum, and make the whole of the bone smooth and practically cylindrical. Do not disturb the rest of the articular surfaces unless you have to. We all know that in extreme cases the big toe is pushed way out of line, and it cannot be brought anywhere near straight without removing some of the articular surface, and in such cases Dr. Mayo's operation is excellent and has proved its use, as emphasized by the speaker; but the inner side of the bone should be trimmed off very carefully. That is the main thing. It is the inner side of the bone that makes the trouble. It is also wise in many cases to excise the thickened skin as well, but this is not always necessary. One must always suture the skin very accurately and it is well to twist bleeding vessels instead of ligating them. It is my personal opinion that you should avoid the Mayo operation in every case you possibly can.

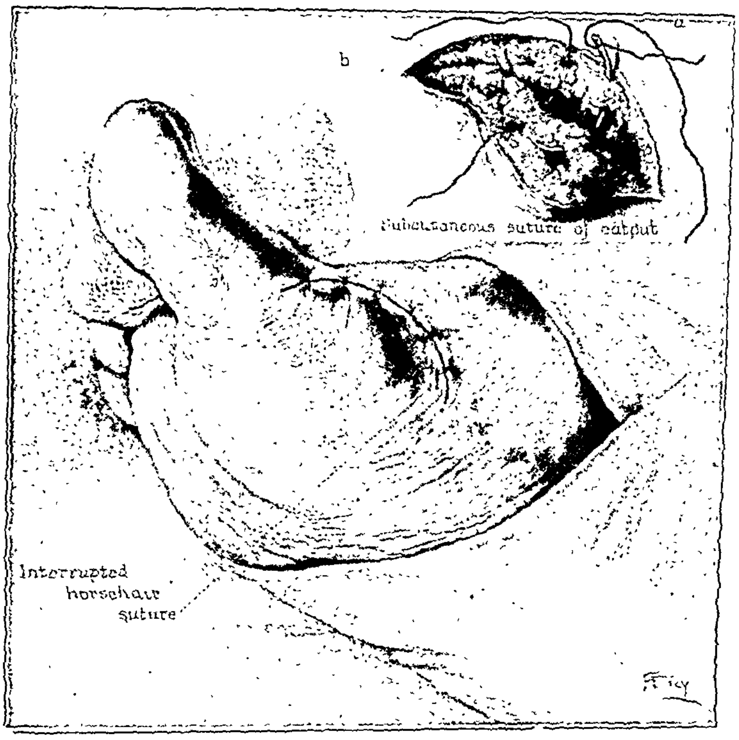

Fig. 5.—*a*, subcutaneous tissue sutured with interrupted catgut sutures; *b*, location of scar where shoe will not press on it. A pad of gauze is placed between the first and second toes to maintain the correct position of the great toe.

Dr. John Ridlon, Chicago: To emphasize the difference of opinion among men working side by side in the same town, I wish to say that I agree with Dr. Ryerson only in one statement; that is, that the Mayo operation should always be avoided. Further than that, I would want to say that I think the Mayo operation a much better operation than the one described to you by Dr. Ryerson. I believe that the success of an operation on a big toe with a bunion or hallux valgus, in order to secure a useful, strong, mobile and painless joint, lies in the taking away of a lot of bone. I remove all of the head, and then some, and all of the knobs, and I am particularly careful to remove any knobs on the plantar surface of the foot.

Dr. J. P. Lord, Omaha: I have performed the Mayo operation since it was first described by Dr. Charles Mayo, and I have undertaken to follow the technic as originally outlined by him, and that technic does not recommend the removal of the whole of the head of the bone—but about three fifths, as I remember it, of the articular enlargement—then the thorough removal of the projecting bone on the inner side, and the following of all of the details. It has never brought me anything but the most complete satisfaction. I think that if too much bone is not removed, the objection raised by Dr. Ryerson, that it is conducive to flatfoot, is not borne out, at least by my experience, and I simply wish to put myself on the side favoring the Mayo operation as being the best procedure for the condition described.

Dr. Leonard W. Ely, San Francisco: There is one point in Dr. Henderson's paper to which I should like to take exception, namely, the causation of a bunion. The simplest things, when we come to examine them, we find are not simple at all. I always assumed that a bunion was caused by short shoes, but people who wear short shoes are not always those who have bunions, and many people who have worn broad shoes and long shoes all their lives have bunions. Young of Philadelphia discovered one cause in a bone which pried the first and second metatarsals apart. Some German observer maintains that a bunion is really not a hallux valgus but a hallux varus, caused by a varus position of the metatarsal bone. He ascribes the ultimate cause of it to an obliquity of the articulation of the metatarsal with the tarsus. That looked extremely probable, and I assembled a great many roentgenograms with the idea of finding out if it was so. It is not, as far as I can make out. It seems to me that our knowledge of this subject will be quickened if we will not assume a cause, but will try to find out the real cause of the deformity, and possibly improve our treatment on that basis. The insertion of a bursa I have never found necessary. I agree with Dr. Ryerson that if one takes off as much bone as is necessary at the end of the metatarsal, one will get a fairly movable joint.

Dr. J. T. Rugh, Philadelphia: I just want to call attention to one little point which I usually have followed in this operation, though the conditions that are present in the individual case should determine the type of the operation. It does not appeal to me to be the best surgery to make the base of the flap anteriorly. The vitality of the flap, I feel, would be endangered. I always make my flap with the base of it posteriorly along the side of the metatarsal to guard against sloughing.

Dr. B. M. J. Conlin, Long Beach, Calif.: Bunions are not caused by either short or tight shoes. After a careful study of bunions for over forty years I have come to the conclusion that they are hereditary. The natives of the Sandwich Islands and the Indians of Mexico, who never wear shoes, have bunions; and the people wearing short, tight, ill-fitting shoes do not have bunions, unless they inherit them. The bunion in the human species is analogous to the ringbone in the horse, and the breeders of thoroughbred horses have demonstrated beyond a doubt that ringbone is transmitted from parent to offspring.

Dr. E. A. Rich, Tacoma, Wash.: In general considerations with regard to feet afflicted with bunions, two facts seem to stand out most prominently; first, a varying degree of flatfoot is constantly present, and second, this flatfoot usually is not of the painful variety. I have in mind cases that present with so marked a degree of flatfoot that the bunion deformity would seem insignificant, yet the bunion is the only part of the foot that causes pain. This fact further illustrates some points recently brought out in the controversy in the columns of The Journal over flat feet, namely, that the degree of flatfoot cannot be gaged by the symptoms. It is my conviction that the flatfoot condition in operative bunion cases does not need treatment and end results will be better if no attempt is made to correct the arch deformity.

We have been doing our own operation on bunions, which is a little more extensive than that of the Mayos. We have taken out more bone. Often the head of the metatarsal has to come out, but usually part of the articulating surface of the joint can be saved. Instead of using the bone clippers we prefer a sharp chisel that will directly cleave the bone and not crush it. We believe that there is less cause for regret when too much bone is removed than when too little is taken away.

Dr. John F. Golden, Chicago: Most of the bunions that have come to me for the last eight years have been operated on according to the method of Dr. Henderson. It occurred to me during the discussion that probably the bunions came earlier to the man in orthopedics and later to the man in general surgery. The bunions that we get are large ones, and usually the foot is markedly flat. In those cases I have acted according to Dr. Henderson's procedure, waiting as long as possible and removing as little as possible, and the results have been very good. I might ask Dr. Henderson in closing this discussion to mention the formation of hematomas, which frequently ensues. We aspirate them about the third day, and we do not touch them with our fingers or with the sutures. Everything is handled with metal; not even touched with gloves. We use ligatures practically not at all, and if hematoma results we simply aspirate that hematoma at the end of the second or third day. I saw Dr. Smith do an operation on a number of stiff fingers, and I noted the analogy between the technic he used and that which is followed by Dr. Henderson in the case of flat feet.

Dr. M. S. Henderson, Rochester, Minn.: I can say that I am just as positive that this method is the best as Dr. Ryerson is that it is not, because I believe the whole thing to hinge on the fact, which I probably did not emphasize in the paper, that the bunion foot is a particular type of foot. The great toe is usually the longest, and it should not be the longest, or at least should not be any longer than the second toe. Now that is not an invariable rule, but in a large majority of cases it is true, and I do not think we can put aside the fact that short shoes produce bunions. They do not always produce them, but they help, and I do not believe a bunion can be cured by the operation Dr. Ryerson describes. Some of the head of the bone—the articular surface—must be taken off to shorten the great toe. Of course, these people come to us in all conditions and the severe type cannot be absolutely cured. They will always have some trouble and we always tell them so, but we *can relieve them greatly*. Many cases can be cured by proper shoes and care of the feet, and on these we do not operate. Dr. Golden mentions hematoma. I think he is quite right. Unless one is very careful, hematoma forms; this should be aspirated about the second day. Dr. Rugh mentions the type of flap. I have tried all kinds of flaps—from the phalanx with the base backwards, with the base below, and I am of the opinion that the flap in front with the base toward the phalanx is the best. I do not believe that it becomes necrotic; at least, I have had no evidence to point that way.

VACCINE TREATMENT OF HODGKIN'S DISEASE

REPORT OF A CASE

A. R. HATCHER, M.D.
AND
W. G. LEMMON, M.D.
WELLINGTON, KAN.

From 1832, when Hodgkin recorded a series of cases, up to 1913, the treatment of Hodgkin's disease was futile, and the outcome fatal. In the acute forms, death occurred in a few months; while in the chronic type, patients often survived two or three years, during which time remissions of symptoms and size of glands were frequent.

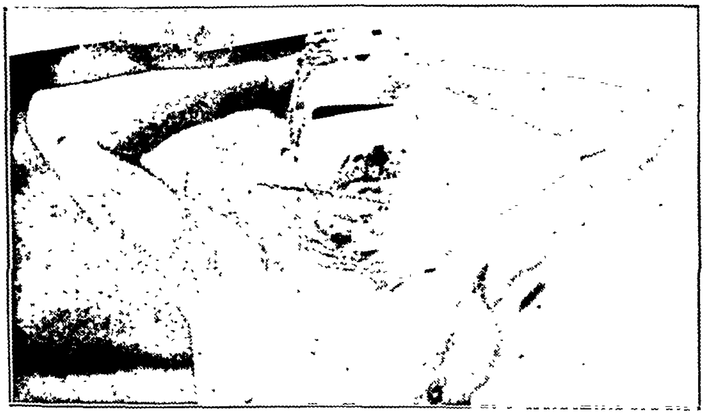

Fig. 1.- -Patient, July 1, 1914, before treatment was begun.

The etiology up to this time was unknown. A few believed it to be a tuberculous or paratuberculous adenitis, some held that it was a form of malignancy, while a few others believed it to be an infection probably entering through the tonsils. In 1910, Fränkel and Much found a gram-positive, non-acid-fast, diphtheroid bacillus in smears from the glands in a series of cases. They believed this bacillus to be the specific cause of the disease. In 1913, Bunting and Yates in America and Negri and Mieremet abroad succeeded in cultivating an organism corresponding to the one found in smears by Fränkel and Much. A little later Billings and Rosenow[1] published results of treatment with vaccines made from the organisms. Their method of preparation comprised growing the organisms on Loeffler's blood serum, ascites agar or blood agar, for from twenty-four to forty-eight hours, suspension in physiologic salt solution, and heating from forty to sixty minutes at 60 C. (140 F.).

---

[1] Billings, Frank, and Rosenow, E. C.: The Etiology and Vaccine Treatment of Hodgkin's Disease, The Journal A. M. A., Dec. 13, 1913, p. 2122.

The case which we wish to report was treated by vaccines and the Roentgen ray. There was an intercurrent acute suppurative appendicitis.

History.—A retired farmer, aged 63, married, who had had rheumatism when a child, and occasional attacks of myalgia since, but no other illness, in the latter part of February, 1914, had what he described as "a breaking out on the face." A few days later he noticed swellings beneath the angles of the jaws and ears; these gradually increased in size, and in two or three weeks, swelling was noticeable in the axilla and groins. The tumor formations were never painful, tender or red. He rapidly became weak and emaciated, and complained of extreme nervousness.

Examination.—Tumor formations as shown in Figure 1 were present. The masses apparently consisted of enlarged discrete, nonadherent, painless lymph nodes. The mucous membranes were pale. Physical examination otherwise was negative.

The urine was pale amber, acid, specific gravity 1.008, albumin and sugar negative. Microscopically there were a few hyaline casts and amorphous urates. The red corpuscles in the blood numbered 3,200,000; hemoglobin, from 55 to 60; white blood cells, 7,200; polymorphonuclears, 59; mononuclears, 41.

Treatment.—In June, 1914, one of the glands was taken from the neck and sent to Dr. F. W. Gaarde of Chicago for diagnosis and preparation of autogenous vaccine.

July 1, 1914, vaccine therapy was begun, consisting of subcutaneous injections twice a week for seven weeks. There were no severe reactions. The initial dose was 25,000,000; this was gradually increased to 2,000,000,000, and in addition to this the patient was given Roentgen-ray treatment every five days for eight weeks. He received six injections before there was any amelioration in the symptoms or the size of the glands. After this they gradually reduced to about two thirds of their original size. August 27, he was taken ill with acute suppurative appendicitis. He was operated on, September 8, and an abscess was drained. The tubes were removed on the eighth day, and drainage ceased about the eighteenth. During this time there was an extremely rapid decrease in the size of the glands. With cessation of pus there was a corresponding slackening in the retrogression of the glands which did not cease entirely, but has continued until the present time.

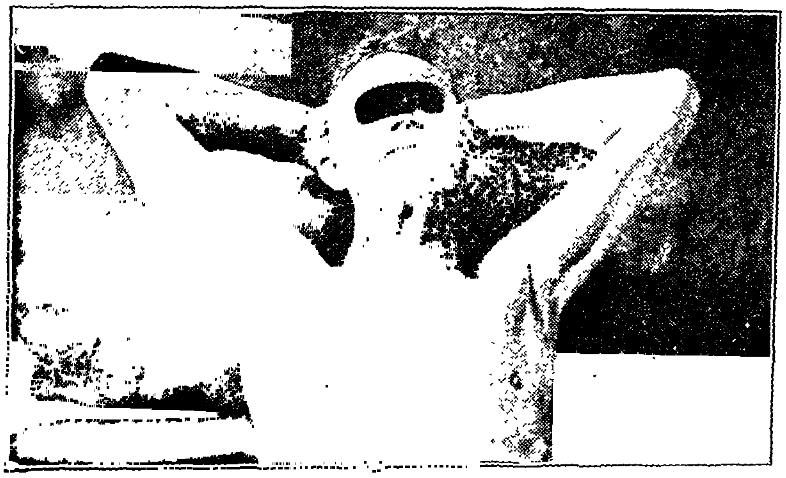

Fig. 2.—Patient, July 1, 1915, showing results of treatment.

Constitutionally, except for a dragging sensation at the site of the scar, the patient feels perfectly well, and is doing his own chore work on the farm.

The question arises as to what influence the pus infection had on the glands. There is no doubt that the toxins from infectious processes at times exercise a profound effect on newly formed tissue, as illustrated by the use of Coley's toxins in sarcoma. The fact, however, that the glands were decreasing under the vaccine treatment, and continued to do so after the infection had cleared up, and that the results are identical with those of Billings and Rosenow, leads us to believe that while the appendicitis may have been a favoring influence, the main results were due to the vaccines.

POLYPUS OF FALLOPIAN TUBE

Lawrence H. Hoffman, M.D., San Francisco
Fellow of the American College of Surgeons

Polypus of the fallopian tube, although mentioned in textbooks of gynecology, is rarely encountered in pelvic surgery. The condition may exist without causing any symptoms and pass unrecognized until it reaches a size to be discovered by palpation during some routine pelvic examination or until the occurrence of rupture of the containing fallopian tube demands operative procedure.

The case I report is interesting on account of its rarity and its simulation of ectopic gestation. I have searched the literature and can find no cases of that nature on record.

History.—The patient, aged 30, married several years, presented herself to Dr. Oscar Mansfeldt with the following history. She had never become pregnant although she had used no preventive measures. Menstruation had always been regular, moderate in quantity, about four days' duration. The April and May menses were normal. The June 1 period was on time but patient menstruated several days longer than usual, with a day's cessation, and a few days of a dark bloody discharge with clots, accompanied by colicky pains in the lower abdomen and slight abdominal distention.

Examination, June 18.—The cervix was conical, of normal consistency. The uterus was normal in size, in axis of pelvis not fixed. A boggy semifluctuating mass was palpable in Douglas' culdesac. The right adnexa was palpable and no abnormality was felt. A mass was felt in the left parametrium about 5 cm. in diameter, immobile, separable from the uterus and tender to the touch. The findings were corroborated by an examination under narcosis June 18, and I was called in consultation to verify the findings. A diagnosis of ectopic gestation was made and operation was decided on and performed June 19.

Operation.—When the peritoneal cavity was opened, by median abdominal incision, some fluid, blood and clots escaped. The left adnexa was represented by a mass 5 cm. in diameter, embedded in blood clots, and ruptured on its superior margin near its distal end. This adnexa was removed typically and the clots evacuated from the peritoneal cavity. The abdomen was closed in four layers. Recovery was uneventful.

The pathologic report, made by Dr. Ophüls, was of rupture of the fallopian tube, which contained a polypus, 2 cm. in diameter, and coagula.

When discussing the case, the existence of ectopic gestation was weighed but the fact that there had been no amenorrhea and that uterine enlargement was absent caused a doubt in our minds. The other symptoms and physical signs were so suggestive of extra-uterine pregnancy that we felt an exploratory operation was demanded, knowing the dangers of such a condition. Until the pathologist's report was received the findings were taken as ectopic pregnancy, and great was our surprise when the true nature of the lesion was disclosed.

530 Butler Building.

Preventive Medicine.—Within the past thirty years in this country the mortality from tuberculosis has been reduced more than half, and with scarlet fever and diphtheria the results have been more striking. Within the past ten years the average life has been increased four years.—Vaughan.

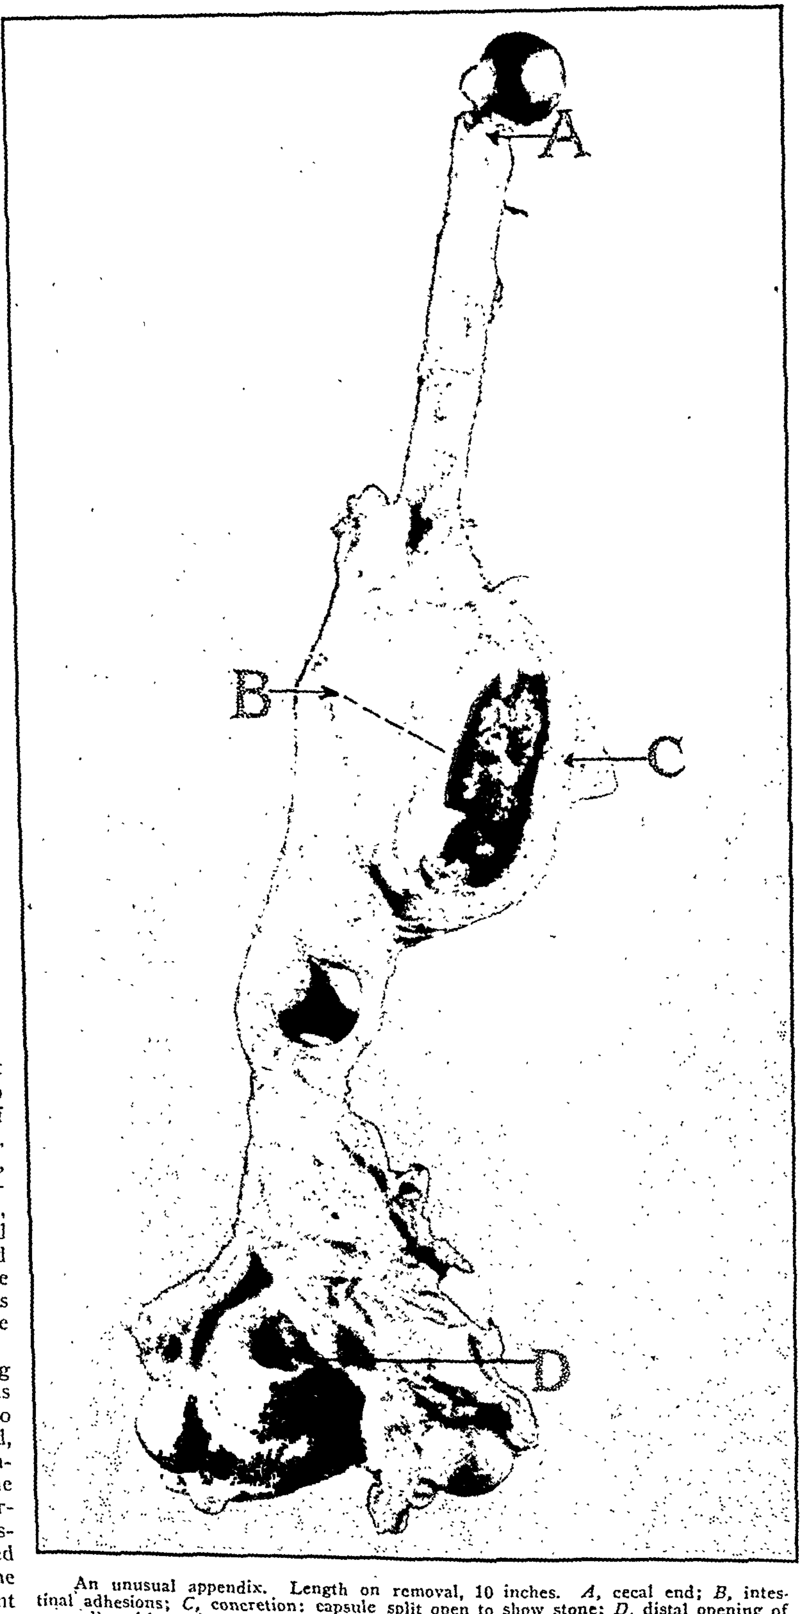
AN UNUSUAL APPENDIX

W. W. Grant, M.D., Denver

The following case is reported because of its interesting and unusual clinical history and remarkable character and dimensions of the pathologic specimen:

G. H., aged 27, came to Colorado in 1907 for a mild tuberculous infection, it is stated, of the apex of the right lung. In 1908 after a year of partial invalidism, he was pronounced well. He has had persistent constipation for ten years with periodic loss of appetite and occasional gastric disturbance, without any assignable cause. For several years past he has been superintendent of mining operations at Creede, Colo. On the night of May 15, 1915, he was taken suddenly with severe pain over the abdomen, which continued for six or eight hours. It was followed by marked tenderness in the lower abdomen for four or five days. Notwithstanding the severity of the attack and tenderness following, he was up and about, and resumed his labors immediately, though he could not straighten his body, on account of discomfort induced, for several days. He then consulted a local physician at his office, who took his temperature and reported it normal. He had no further reminder of trouble until July 25, when, in bed at night, he had the second attack of more intense, acute pain which lasted eight hours. He called no physician and the following morning was up and about as before in every particular.

In ten days, feeling that the trouble was serious, he came to Denver and consulted, at first, two distinguished internists. One thought, from the personal and clinical history and the localized swelling with some glandular involvement in the abdominal wall about the mass, that it was probably tuberculous. The other thought it was connected with the appendix in some unusual way, but its exact character doubtful. He was then referred to me. A well-defined mass, the size of the clenched fist, just below the umbilicus, with its center at the right border of the right rectus muscle, was manifest on palpation. A few slightly enlarged lymph glands could be felt about the mass in the wall of the abdomen. Only slight tympanitis existed. The temperature was 98, and pulse normal. The mass was fairly well circumscribed and extended deep into the cavity of the abdomen. The clinical history and immediate subsequent events were so characteristic of the pain and history of a perforative appendicitis with protective adhesions, that I had no doubt as to the diagnosis though recognizing that tuberculous history might have had some influence in the case.



An unusual appendix. Length on removal, 10 inches. *A*, cecal end; *B*, intestinal adhesions; *C*, concretion: capsule split open to show stone; *D*, distal opening of appendix with perforation.

I operated on him August 7 at St. Luke's Hospital. Temperature 98.2. Incision to the right of the rectus. With the opening of the peritoneum about a pint of bloody serous fluid escaped, due, doubtless, to the pathologic condition of the omentum and partial constriction of the adherent intestines. There were no enlarged mesenteric glands, or other evidence of tuberculosis. The ill-defined mass was covered by partially gangrenous omentum in front, and on all sides was protected by closely adherent small intestines extending to the posterior wall of the peritoneum. By delicate dissection the intestinal and mesenteric adhesions were released from the tumor. During this performance about 1 ounce of colon bacillus pus gradually escaped, but it did not enter the peritoneal cavity. When the body of the tumor was freed the upper portion of the appendix was stripped of adhesions, and as soon as severed from the intestine a very mobile cecum was observed, with no adhesions above the stump of the appendix. When removed the latter measured 10 inches in length. A drainage tube was inserted and left for five or six days. The temperature was normal throughout the convalescence and the recovery was uneventful.

The exterior of the concretion is a hard shell about one sixteenth of an inch thick, with a distinct metallic ring when tapped with a scalpel. The color is yellow, resembling that of cholesterin, and the surface, as shown in the illustration, is thickly studded with sharp spines resembling a cockle burr. The interior was of a soft, putty-like consistence and was not further examined as I desired to preserve the specimen, the size of a large hickory nut, intact. I have never before seen a case with this pathologic condition, of years' duration doubtless, with such a negative clinical history with the exception of the two brief attacks of pain due to perforation. On September 4 he returned to Creede feeling quite well and the wound had perfectly healed.

Mack Block.

TWO FAVUS FAMILIES

J. E. Lane, M.D., New Haven, Conn.

Favus is not a rare disease in this country and there are usually a few cases in all of the dermatologic clinics of our larger cities. In the parts of Europe where it is most prevalent it is a disease of the country rather than of the city. This is probably due to the fact that the families of the peasants live more closely crowded together and under less sanitary conditions than does our rural population. Still the fact that favus has never become common in this country is largely due to the rigid exclusion by the federal authorities of immigrants affected with it.

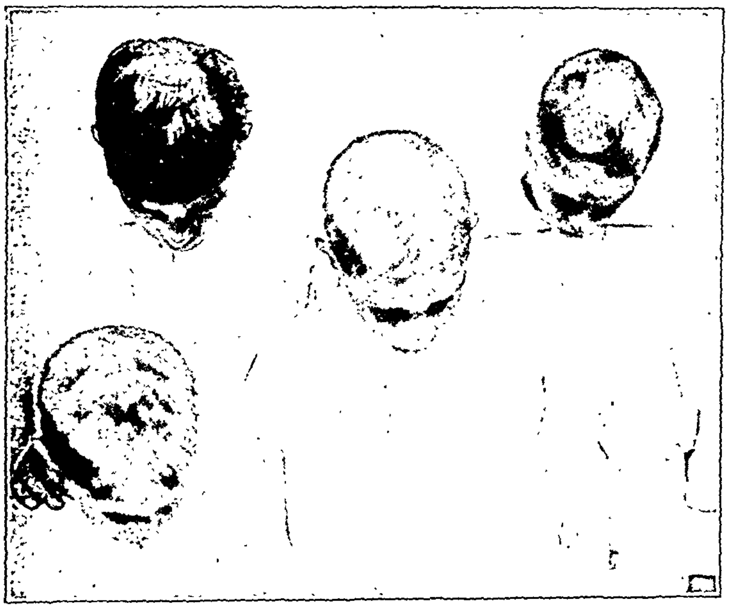


Fig. 1.—Favus in a family of nine, five of whom had the disease.

The following cases illustrate the effect of not properly treating every patient with favus as soon as it is discovered, and the fact that the importance of such treatment is not sufficiently realized in places where it is a rare disease. They also illustrate the fact that favus frequently originates in this country. The impression is still prevalent among many physicians that nearly all cases of favus are found in immigrants, though as long ago as 1896, this was shown by Wende of Buffalo not to be the case. Another point of interest is the rather unusual number of individuals of the same family affected, and the extent of the disease in them.

A few months ago my attention was attracted to the subject by a case of favus in a boy 13 years old, who for five years had been occasionally coming to the dermatologic clinic of the Yale Medical School. A visit to his home disclosed the fact that there were nine children in the family, of whom four others, children aged 10, 8, 6 and 2 years, were affected. The boy of 13 was nearly bald. The disease in the child of 2 was not extensive. In the others, practically the whole of the scalp was involved. None of them had been treated at all except the boy of 13. All of these cases developed in this country, the parents having come from Italy twenty years ago. The extent of the involvement is shown in Figure 1, the photograph having been taken after the removal of the crusts. (In neither family was I ever able to get all five of the children together for a photograph.)

The second family was also Italian, and the parents also came here about twenty years ago. It was discovered by the Visiting Nurses' Association, which had been caring for the other family. In this family there were five children of the ages of 12, 8, 6 and 4 years, and a baby of 10 months. All of the children had favus, and they presented a disgusting appearance, well shown by Figure 2, which was taken before any attempt at cleaning had been made. The scales on the girl's dress, which fell when her cap was taken off, show the ease with which she could scatter the disease if opportunity offered.

All of these cases originated in this country, and I subsequently found out that some of them had been discovered more than five years previously. As favus is not a reportable disease, nothing was done about them, and it was allowed to spread, with the results described. Children with favus are excluded from school, so with the exception of the boy of 13, who at some time or other had been in school for about six months, none of them had ever been in school at all. With the same exception, none of them had had any treatment.

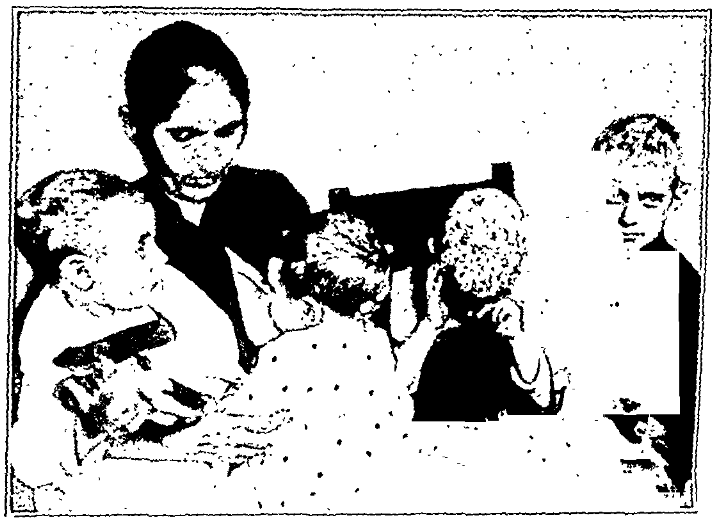

Fig. 2.—All of the five children of this family, of whom four are shown, had favus.

Such a condition not only deprives its victims of an education, but if allowed to continue, deprives them, on account of their disgusting appearance, of practically all means of earning a living until the disease has eradicated itself, which in some cases is not before old age.

It is obvious that favus should be made a reportable disease, and that each case should be properly treated as soon as it is discovered.

Partial Refrigerating Process to Aid in Transportation of Milk.—Our Italian exchange, *Pediatria*, describes a method for keeping milk for long transportation, which has been introduced into the Brazilian province of Minas-Geraes, noted for its dairies. The principle is to cool the milk after pasteurization and pour it into a 300-quart can already containing blocks of frozen milk. The milk is frozen in blocks weighing 22 or 33 pounds, and ten or twelve of these blocks are placed in the large can, which has insolating walls, and the chilled and pasteurized milk is poured over them. Milk which has been thus sealed is said to keep for fifteen or twenty days. When the can is opened the milk is found homogeneous and is said to resemble in every respect the freshly drawn product.

New Instruments and Suggestions

A NEW NECK BANDAGE

A. G. Bettman, M.D., Portland, Ore.

Realizing how difficult it is to apply a dressing high up on the back of the neck and keep it there by the means generally used, I have devised a very simple bandage to accomplish this object by the following procedure:

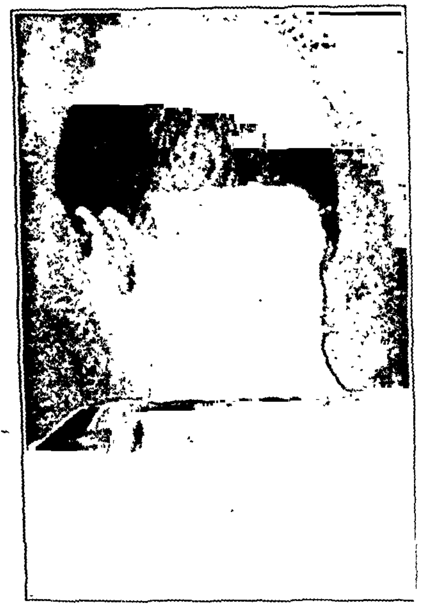

Fig. 1. — Dressings, cardboard and two turns of bandage in place.

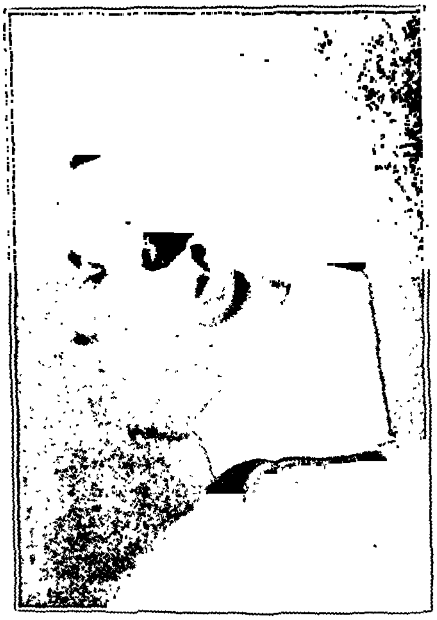

Fig. 2.—Side view of completed bandage.

Put on the dressings in the usual way. Apply a 2-inch bandage twice around the neck, folding it on itself lengthwise the second time around.

Cut a piece of stiff cardboard of suitable size and shape, as shown in Figure 1. Place the lower end of the cardboard in the fold made in the second turn of the bandage. Continue bandaging over the cardboard, fixing an occasional turn over the top. Figure 2 shows the completed bandage.

This bandage I have found very serviceable, especially where the patient objects to having the bandage around the forehead, and adhesive plaster is unsatisfactory.

The advantages are: The bandage is easily and quickly applied. It looks neat and can be made as high as required. It holds the dressings in place. It is not objectionable to the patient. There is no adhesive plaster to annoy the patient.

809 Stevens Building.

A SELF-ILLUMINATED BERGER LOUPE*

Edward A. Shumway, M.D., Philadelphia

I desire to show a simple modification of the Berger loupe, which consists in the attachment to its side of a brass clip to hold the small flashlight, which has the appearance and size of a stylographic pen. The light has a small, one-cell battery, which illuminates a tungsten filament lamp, and has a permanent turn-on arrangement. It can be purchased at any of the electrical supply houses, or instrument shops.

The light rays from the lamp are projected toward the focal point of the Berger loupe, and give sufficient light to illuminate satisfactorily the eye under examination. It has been of especial value, however, in the removal of foreign bodies from the cornea, and in pulling out delicate misplaced cilia from the eyelids, as it gives an independent source of illumination, and leaves both hands free for manipulation of the eyespud, and for holding the patient's eyelids. It has also the advantage of being independent of wires to batteries or rheostats, and can be readily removed from the loupe when illumination is not required.

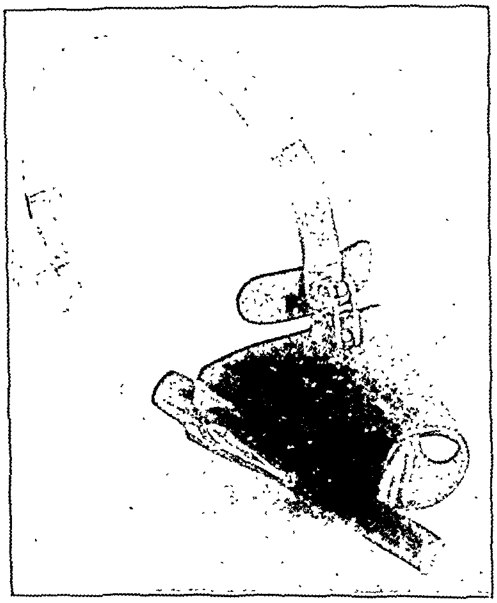
The Zeiss loupe has also a lamp to illuminate the eye, but the instrument is much more expensive, the lamp requires a separate battery or rheostat, and moreover, the focus is rather short—1¼ inches—while the Berger loupe

focus is rather short—1¼ inches—while the Berger loupe

focuses at about 2 inches, giving more space in which to move the spud, or other instrument.

Other arrangements have been employed to illuminate the eye in removing foreign bodies, but they are not sufficient, when the operator requires binocular magnifying power to assist his near sight, and self-illuminated spuds have been unsatisfactory, in my experience, as the illumination is not constant, but varies with the distance of the spud from the eye. Moreover, it is very difficult to get patients to hold their eyes still, as they seem to fear a shock of some sort, when the light from such an instrument, connected by wires to a battery or rheostat, approaches the eye.

The ordinary tungsten lamp furnished by the Ever Ready Company has a plain glass top. For more powerful illumination I have replaced it by an imported lamp, which has a small magnifying lens fused on the top, by means of which the light rays are better concentrated. This makes the apparatus more useful in dispensary work, especially in the examination of inflammatory conditions of the anterior portion of the eyeball or its adnexa, making it usually unnecessary to take patients to a dark room. The loupe has been cut out on each side to remove the obstruction to lateral vision, of which complaint is occasionally made, but this is not a new feature.



Self-illuminated Berger loupe.

The modified apparatus can be obtained from Wall & Ochs, Philadelphia, who will attach the clip and lamp, or furnish the entire outfit.

2007 Chestnut Street.

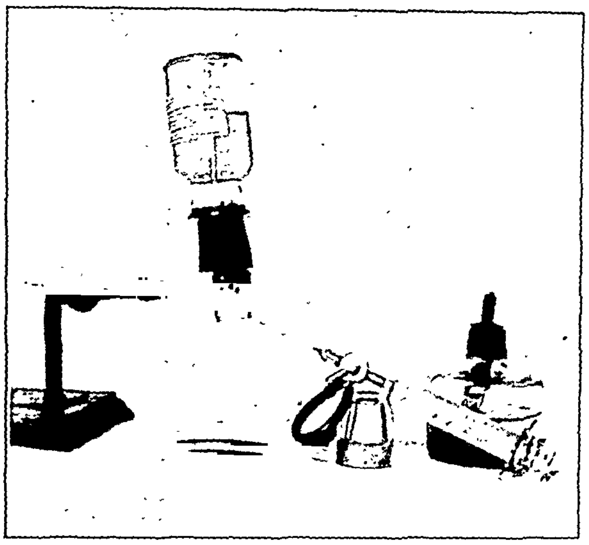
RAPID INOCULATION OF LARGE NUMBERS WITH TYPHOID IMMUNIZING VACCINE

E. W. Cleary, M.D., Sugar Pine, Calif.

The immunization of large forces of laborers to typhoid fever by inoculating each individual with the routine series of three doses of prophylactic vaccine is a problem which presents distinct difficulties to the physicians who have to meet it. It is not at all to be compared with the task of the army medical officer, whose patients march with military precision at the hour and to the place which he dictates.

Many workingmen who do not object to vaccination are too inert to go to the doctor's office to be inoculated, or come straggling in at irregular hours, forgetting their appointments for successive doses, and in sundry and several ways dragging out the process of immunization to an impracticable length. Yet a large majority must be immunized in order to render their community reasonably safe. To get such a majority it is necessary to go to the men and inoculate them when they are gathered together for work. Employers naturally object to shutting down a large plant to give opportunity for wholesale vaccination of employees, and, in consequence, vaccination must be done either during the noon hour or at night as the men are leaving their work.



Apparatus used in rapid inoculation of typhoid prophylactic vaccine.

A method of vaccination practicable under such limitations must be safe, simple and rapid. It must be safe outdoors or in dusty buildings, simple enough to be carried out by one physician with untrained assistants, and rapid enough to accomplish the inoculation of a large number in a very short time.

I have used the apparatus shown in the illustration in about 300 cases with entire satisfaction. The apparatus consists of a 5-c.c. Lüer syringe, a three-way metal stopcock, a platinum intramuscular needle (the smaller needles were found too fragile), a No. 18 French soft rubber catheter and a cork pierced by one long and one short glass tube. These articles are all sterilized by boiling. The vaccine bottle used was the 2-ounce, wide-mouthed, prescription bottle in which the sterile vaccine was supplied. When one such bottle was emptied, the cork connected to the syringe was simply transferred to a full bottle. The illustration shows arrangement of syringe, stopcock and needle with catheter connected to a third way of stopcock and, by its other end, to the short glass tube passing just through the cork of the vaccine bottle. The longer glass tube extends above the surface of the vaccine in the inverted bottle, and serves as a vent. If there is any question of contamination of the vaccine from air entering through this vent, it can be loosely plugged with sterile cotton. When one is working in a draft, it is best to provide a shield for the alcohol lamp used for flaming the needle.

When one is vaccinating with this apparatus, three assistants are employed. The first rolls up the sleeve and touches the arm with tincture of iodin, the second shakes the inverted vaccine bottle constantly to insure an even suspension of bacteria, and the third keeps the records. With the third way of the stopcock open, the syringe is filled from the vaccine bottle, then the third way closed, and the channel to the needle opened by giving the lever of the cock a quarter turn. As the vaccine enters by gravity into the syringe through the larger opening in the stopcock, absolutely no air is drawn into the syringe, and the plunger may be pulled back with one rapid stroke, filling the syringe barrel accurately to the 5-c.c. mark. One c.c. of the vaccine is injected just beneath the skin through the iodized area over the insertion of the deltoid. The needle is flamed over the alcohol lamp before each injection. In using the 5-c.c. syringe, five men are inoculated before the syringe is refilled. It was found that by doing this, five or more injections could be made per minute, thus giving little time for uneven dosage to result from settling in the syringe. When injections are made slowly, it is better to use a small syringe and fill for each injection.

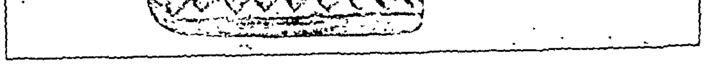
The advantages of this method over the method in which the vaccine is drawn into the syringe by thrusting the needle through the rubber cap of the vaccine bottle are obvious. Any one who has filled a vaccine syringe by the last-mentioned method knows that more or less air is drawn into the syringe, and that on this account much time is consumed in adjusting the syringe load for accurate dosage.

The rapidity of the method described in this paper made it possible, without compulsion, to immunize so large a proportion of the working men in the community in which it was used as to insure against a repetition of such a disastrous typhoid epidemic as had paralyzed industry and taken a toll of several lives from the neighborhood several years before. The extreme simplicity of the operation and the rapidity with which it can be done so minimizes the conception of the serious nature of the process in the minds of the workingmen that many submit who would recoil from a slower or more complicated procedure. The fact that out of a total of nearly 900 doses injected not a single infection, nor even a single unduly severe reaction, occurred evidences the safety and accuracy of the method. The Gay-Claypole vaccine furnished by the California State Board of Health was used.

NEW ARTERY FORCEPS

Carleton Dederer, M.D., Los Angeles
Clinician in Surgery, Los Angeles Department, University of California Medical College

Kocher overcame the difficulty of having the jaws of artery forceps slide across each other laterally by devising the "mouse tooth" at the end. In this pair of forceps nature is imitated by the formation of jaws and teeth which bite firmly without incising. This has been done by making on one jaw a double row of pyramids quite similar in shape to the famous Egyptian pyramids and on the other jaw a series of complementary impressions, all of which give a bite which can be regulated in intensity by the degree of pressure applied.



New artery forceps and magnified model of a portion of one jaw.

This forceps is 6½ inches long and has the new style handle[1] eliminating all acute angles where sutures, ligatures and instruments usually catch.

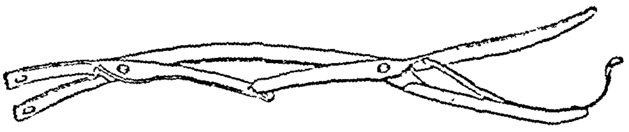
TONSIL FORCEPS

W. P. Megrail, M.D., Wheeling, W. Va.

This instrument is curved throughout its entire length so that a large part of it and the operator's hand is entirely outside the line of vision, which gives an unobstructed field for operation. It has a compound lever handle which makes a firm grip on the tonsil with a very slight grasp of the fingers. The handles work close, permitting the tonsillotome or snare to be readily passed over them. It also may often be found to be a useful instrument for extracting foreign bodies from the pharynx or esophagus.



Tonsil forceps which may be used for extracting foreign bodies from pharynx or esophagus.

Penn and Zane Streets.

A SIMPLE METHOD OF TRANSFUSION IN HEMORRHAGE OF THE NEW-BORN, WITH REPORT OF A CASE

W. S. Howard, M.D., Chicago

The only apparatus required in this method is a 20-c.c. ground glass syringe with a needle 2 or 3 inches long.

After sterilization of the syringe and needle, 2 c.c. of a 10 per cent. sodium citrate solution is drawn into it. The needle is then inserted into the vein of the donor, the syringe filled and withdrawn. The anterior fontanel region of the infant having been previously cleaned with alcohol and tincture of iodin, the needle is pushed into the superior longitudinal sinus and the syringe emptied. This may be repeated several times if necessary. A smaller needle than the one for the sinus may be used on the vein of the donor if desired.

For entering the sinus the needle is inserted at the superior angle of the fontanel at an angle of about 25 degrees with the scalp. When the needle enters the sinus there is a distinct sensation of decreased resistance perceptible. The sodium citrate solution is used to prevent the rapid coagulation of the blood. Two c.c. of a 10 per cent. solution will make the entire contents of the syringe contain only 1 per cent. of sodium citrate, which has apparently no deleterious effect on the blood.

The advantage of this method is the extreme simplicity of technic. It can be done at almost any place, on short notice, with very simple apparatus, and does not require any great amount of surgical skill for its execution.

The use of the longitudinal sinus in infants for aspiration, infusion and transfusion has been recommended by Helmholz (*Am. Jour. Dis. Child.*, September, 1915, p. 194) and Unger (The Journal, Feb. 13, 1915, p. 582). Unger's method for transfusion requires a special apparatus which is described in the article referred to.

REPORT OF CASE ON PEDIATRIC SERVICE OF DR. F. X. WALLS

Baby B., boy, colored, was born at St. Luke's Hospital, Sept. 7, 1915. Labor normal. Birth weight 6 pounds, 11 ounces. Apparently normal in every respect. The mother is a quadroon, aged 30. Had measles during infancy. Has always been in good health ever since. Has had four children and one abortion at third month. All labors have been normal. Second child died at age of 2 months, of malnutrition. Had the abortion in 1910, one year following the birth of the third child. Father is colored, aged 44; has always been well with exception of slight gastric disturbances.

Patient was apparently normal until the morning of Sept. 9, 1915, when there was a very free hemorrhage from the bowels. This was of a rather bright red color and estimated to be at least an ounce in quantity. At 11:45 a. m. a similar hemorrhage occurred. The infant at this time seemed to be in very poor condition. It was very restless and irritable. There were convulsive movements of the arms and legs, and it yawned constantly. After consent of Dr. Walls had been obtained, 18 c.c. of blood were transfused into the longitudinal sinus by the method described above, the donor being one of the nurses. At 12:40 p. m. another free hemorrhage occurred, and again 18 c.c. of blood were transfused, the donor this time being the father. By this time the baby was in a more apathetic state. It promptly regurgitated all food, the emesis being of a dark color. At 5 p. m. the third free hemorrhage occurred, and 18 c.c. of blood were again transfused from the first donor.

Following this there were slight passages of tarlike stools but no more hemorrhages.

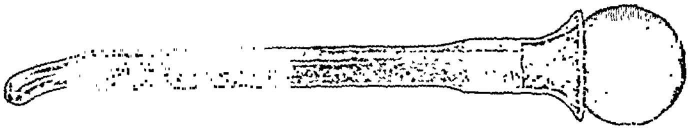
The following day the stools were yellow, the emesis had ceased, and the general condition was much improved. There have been no further evidences of hemorrhage up to the present time. The infant nurses well, has no discomfort following, and is apparently normal in every respect.

St. Luke's Hospital.

URETHRAL SYRINGE

F. A. Van Buren, M.D., Omaha

This syringe was designed for treatment of the female urethra, especially in gonorrheal infections. It is difficult to get a satisfactory syringe, of the piston type, which is positive in action. If the piston is tight enough to insure nonleakage the action is so stiff that one cannot accurately control the pressure or the amount of medication injected. This instrument possesses these advantages over the push type: It is inexpensive, easily cleaned and sterilized by boiling, and is positive in action for the life of the instrument as new bulbs may be obtained. A small hole in the neck of the bulb prevents medication from entering the bulb, thus permitting injection from any position; the tip has the correct curve and caliber for the female urethra. A little pressure against the meatus prevents the fluid escaping, dilates or irons out all folds in the mucosa, thus permitting the fluid injected to reach all parts; more pressure will force the fluid into the bladder if desired.



Syringe designed for treatment of urethral infections in females.

468 Brandeis Theater Building.

Health on the Farm.—The death rate in the rural communities of New York state is higher than that of the crowded city of New York. It still amounts to about 15 per thousand since 1900, while in the city of New York the death rate has dropped about one-third in the last fifteen years. The New York State Department of Health in *Health News* has published papers by various experts to enable the farmer and the country dweller to improve health conditions. It is said that the farmer must be his own sanitary engineer and board of health to a large extent. Among the things he must look out for are proper disposal of wastes, pure water and milk supplies, freedom from insect pests, habits of personal cleanliness, and moderation in all things. The bulletin contains papers by L. H. Bailey on "Good Health and Good Farming," by Henry N. Ogden on "The Farm Water Supply," by Theodore Horton on the "Disposal of Human Excreta and Sewage of the Country Home," by Dr. Alvah H. Doty, New York, on "The Extermination of the Mosquito," and by Dr. William B. May, Albany, on "Health Conditions on Picnic Grounds."

Therapeutics

PLANT POISONING

PRIMROSE

This poisoning is not infrequent, though generally perhaps it is unrecognized, the condition being called acute eczema.[1]

Sharpe[2] thinks that the dermatitis not infrequently seen on the hands of milkers may sometimes be due to the fact that the poisonous substance of the wild primrose is carried on the udders of the cows.

It has been noted that primrose plants do not readily become infected with insects. Montgomery[3] thinks that the cause of this immunity may be the poison exuded by the plants.

The hands and arms are the parts most attacked by the primrose, and the symptoms are burning, puffing, and at times small pin-point blisters. There is also a good deal of itching.

The primary treatment is to recognize and remove the cause. Magnesium sulphate solutions are generally satisfactory in relieving the inflammation. As is true of all acute skin eruptions, catharsis and a milk and cereal diet will hasten the recovery.

IVY, OAK AND SUMACH

While on the subject of plant poisoning it may be well to recall the experimental work done on this subject by Adelung[4] two years ago. Though these plants differ botanically, Adelung finds that their poisonous juices are chemically identical, and this poison is nonvolatile. It has been shown that as little as $1/1000$ of a milligram may produce a dermatitis.

It is now known that the poison of the ivy is of a resinous nature.[5] As it is generally agreed by analysts that the poison is nonvolatile, the assertion that certain susceptible persons may be poisoned by simply passing by the plants remains to be explained. It is certain that neither the pollen nor the plant hairs are toxic,[6] so that direct transmission is the only plausible explanation. As previously shown,[7] Adelung also found that the poison was purely a local one. It is not distributed by the blood.

The latent period or length of time from the infection to the development of the dermatitis is shorter on the parts of the body where the skin is the thinnest, such as the face and the inner sides of the arms and wrists. As is well known, there is a varying susceptibility of individuals, though there seems to be no natural immunity (as shown experimentally). It is a popular idea, however, and seems to be a fact, that some persons may handle the poison ivy, for instance, with impunity. On the other hand, susceptible persons seem to vary as to their susceptibility in different seasons or in different years. This may be entirely due to the variability of the irritant poison.

Adelung found that the rhus plant would yield a pure toxin of about $1/1000$ of its weight. He believes this toxin has a selective action for the epithelial cells. Experimentally Adelung could not demonstrate that immune bodies were formed in the blood or that there were any immune bodies contained in the blood of an individual who was more or less immune to the poison.

Treatment.—If, immediately after exposure to the poison, the parts supposed to be affected are washed with soap and hot water, dermatitis generally will not occur. If it is known that just one small part of the body, as one part of the hand or finger, has touched the poison, the full strength tincture of iodin applied to the part will destroy the poison, according to Adelung.

Protection against poisoning is more or less furnished by oils or fats, as cottonseed oil, smeared over the exposed parts of the body. Any one who is susceptible to such poisoning and knows that he has been exposed, should use, besides the local soap and water, a general hot bath, and should be sure that the possibly infected outer clothing is not again worn until thoroughly brushed and aired.

A strong solution of magnesium sulphate is perhaps one of the best local applications for the dermatitis when it develops. It relieves the itching and limits the inflammation. Other more or less successful treatments are oil or ointment containing ichthyol, potassium permanganate solutions, or the old lead and opium wash. Many people, however, are very susceptible to lead solutions unless they are very weak, and also if the skin is broken too much absorption of lead may occur. As just advised, the magnesium sulphate solution is probably the best treatment. As soon as the acute inflammation is over, any simple talcum powder, or powdered corn starch, is very soothing to the skin.

SUDDEN HEART FAILURE

A correspondent requests a discussion of "an efficient treatment for sudden cardiac failure."

No dogmatic rules can be laid down for the treatment of this condition. The following are suggestions:

1. Put the patient flat on a bed, with the feet elevated, unless it is a case of cardiac dyspnea, in which case he should recline on several pillows.
2. Put a hot water bag over the cardiac region.
3. Use smelling salts for quick momentary stimulation.
4. Give one-half a teaspoonful of aromatic ammonia, in twice the amount of water, if it is at hand.
5. Strychnin sulphate, $1/30$ grain, may be given hypodermically as a stimulant to the central nervous system and to the cardiac nerves.
6. Hot coffee may be given by the mouth.
7. An injection of the contents of an ampule of camphor in oil may be given intramuscularly.
8. Epinephrin may be given in a dose of 5 drops on the tongue, which may be repeated in half an hour if advisable.

All of the foregoing are quick-acting treatments.

9. A little slower than these is the blood-pressure-raising substance of the posterior lobe of the pituitary gland. An ampule of this liquid may be injected hypodermatically, and repeated in two or three hours, if needed.
10. A little slower to act are the contents of a sterile tube of strophanthin, given intravenously. This must not be given if the patient has been taking digitalis, and should rarely be repeated.
11. Slow to act, but projecting its influence for nearly twenty-four hours, is digitalis, best in the form of an ampule of digipuratum fluid, given hypodermically. This should ordinarily be given but once

in twenty-four hours, and certainly not repeated for twelve hours.

12. With low blood-pressure and a fairly strong heart an aseptic preparation of ergot, given intramuscularly, is often of great value in aiding to save a patient with heart failure.

It is hardly necessary to urge that the cause of the heart failure be determined. A quick blood count will show whether or not there is internal hemorrhage.

Of course it is not necessary to use all of the above-mentioned drugs, and they are only suggestions.

More detailed discussion of "Acute Heart Attacks" and of "Shock" will be found in The Journal, "Disturbances of the Heart," Dec. 21, 1912, p. 2256, and March 29, 1913, p. 996, respectively. A short discussion on "Heart Tire" appeared in this department, Oct. 2, 1915, p. 1184.

HEMOPHILIA

In a severe case of hemophilia in a child of 8, after having carried out the measures usually employed without satisfactory results, a physician asks for suggestions as to treatment and references to recent literature. The following may be offered:

When the part can be reached externally, bleeding may be stopped by pressure, by suprarenal solutions, by hydrogen peroxid solutions, sometimes by gelatin, by thrombokinase in the form of extract of lymph glands, thymus, testis or other source of nucleoprotein, and by many iron salts. It is not desirable to use iron if it can be avoided on account of the disagreeable coagulum that forms and the danger of infection and suppuration underneath.

Bleeding from the stomach may be temporarily stopped by ice, suprarenal solutions, and tannic acid.

The tendency to bleed is due to a blood dyscrasia, and can be prevented only by a change in the character of the blood. Calcium, in the form of calcium lactate or calcium glycerophosphate, may be of value, and its administration for a few days may sometimes prevent profuse bleeding in bleeders, even during or after an operation. A diminished amount of calcium in the blood may be due to increased loss of calcium. Overactivity of the ovaries in adult females, it is said, increases the loss of calcium and the bones become soft. The parathyroids are also believed to have something to do with calcium supply and elimination. It is possible that feeding parathyroid gland substance in hemophilic children may be of value.

The feeding of suprarenal gland has been unsuccessful. The blood-vessel-constricting principle of the suprarenal gland is absorbed from the mouth or mucous membranes, or will act for a short time when injected subcutaneously, but suprarenal, as a whole, when fed, seems to be of little value. The blood pressure raising stuff does not act after the suprarenal substance has been swallowed into the stomach; at best, it acts only locally. Though in normal individuals, especially women, thyroid substance tends to promote bleeding, instances occur in which it seems valuable in stopping bleeding. Just what other glands are stimulated by feeding thyroid, with the effect of changing noncoagulable blood, is not known. It is, however, a clinical fact that not infrequently profuse bleeding is stopped by the feeding of thyroid.

As pituitary substance from the posterior portion of the gland is known to stimulate the suprarenal glands, it might be logical to feed this substance.

The most successful immediate treatment of profuse hemophilic bleeding is blood serum. The serum may be prepared from any human being, a relative often preferred, whose blood shows normal coagulability. A number of cases of successful treatment with blood serum are now on record.

Horse serum also seems to be successful, given subcutaneously, as is diphtheria antitoxin.

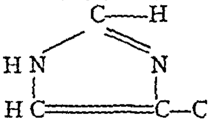
New and Nonofficial Remedies

The following additional articles have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Their acceptance has been based largely on evidence supplied by the manufacturer or his agent and in part on investigation made by or under the direction of the Council. Criticisms and corrections are asked for to aid in the revision of the matter before publication in the book "New and Nonofficial Remedies."

The Council desires physicians to understand that the acceptance of an article does not necessarily mean a recommendation, but that, so far as known, it complies with the rules adopted by the Council.

W. A. Puckner, Secretary.

HISTAMINE HYDROCHLORIDE.—



$-CH_2.CH_2.NH_2.HCl$.—The hydrochloride of the base beta-iminazolylethylamine (histamine). Histamine is closely related to histidine, from which it differs in that one molecule of carbon dioxide has been eliminated.

Actions and Uses.—Histamine hydrochloride has a powerful contractile action on certain muscular fibers and a strong vasoconstrictor action. The available evidence does not warrant a recommendation for its therapeutic use, but it is a valuable reagent for the standardization of pituitary and similar preparations.

Histamine was first prepared synthetically from iminazolylpropionic acid by Windaus and Vogt in 1907 (*Ber. d. deutsch. chem. Gesellsch.*, 1907, xl, 3691); it was then prepared by bacterial putrefaction of histidine in 1910 by Ackerman (*Ztschr. physiol. Chem.*, 1910, x, 504) and isolated from ergot in 1910 simultaneously by Kutscher (*Zentralb. f. Physiol.*, Vol. 24, p. 163) and Barger and Dale (*Pharm. Jour.*, June 4, 1910, p. 710; June 18, 1911, p. 757).

Histamine hydrochloride melts at 240 C. (Corr.).

When picric acid is added to an aqueous 1 per cent. solution of histamine hydrochloride, histamine picrate is precipitated promptly; the precipitate should melt at 234 C. (Corr.). Any impurity present in the histamine hydrochloride will prevent or at least very much retard the precipitation of this picrate.

If a 1: 1,000 solution of histamine hydrochloride is made alkaline with sodium hydroxide and a solution of diazobenzosulphonic acid (Pauly's reagent) made alkaline with sodium hydroxide be added, a cherry red color appears.

If a 1: 1,000 solution of histamine hydrochloride is mixed with an excess of bromine water, then boiled until the bromine is evaporated and sodium hydroxide added to the solution, a black discoloration occurs.

Proprietary Preparations:

IMIDO Roche.—A name applied to histamine hydrochloride.

Manufactured by F. Hoffmann-LaRoche and Co., Basel, Switzerland (Hoffmann-LaRoche Chemical Works, New York). No U. S. patent or trade-mark.

Ampules Imido Roche.—Each ampule contains 1.1 Cc. of an aqueous 1: 1,000 solution of imido Roche (1 Cc. contains 1 mg.).

THE PROBLEM OF RURAL HEALTH ADMINISTRATION

The problem of securing efficient administration of public health laws is especially difficult in the rural districts. City and town can today obtain the best health service for which they are prepared to pay. The small community, on the other hand, unless the circumstances are exceptional, cannot command the various kinds of expert knowledge, medical and sanitary, chemical, bacteriologic, engineering and statistical, which are essential for the adequate handling of its problems.

Attempts along several different lines have been made to meet this need. In many Southern states, health officers are provided for on the basis of county units. In Massachusetts an interesting plan of voluntary community cooperation has been worked out under the guidance of the public health faculty of the Massachusetts Institute of Technology. The most promising plan of all is perhaps the organization of a corps of state sanitary supervisors, acting under the direction of the state board of health and bringing to the support of the local health officer the technical knowledge and the moral support of the entire state.

This system has been in force in Massachusetts, in one form or another, for nearly ten years. It has been incorporated in the new public health law of Maryland, and two years ago was made part of the model health law of New York State.

Those who have followed the development of state health organization in this country noted with satisfaction how the attacks made by the legislature on the New York health law last spring were in the main brought to naught by the remarkable support which that law received from the press and the people of the state. What the politicians dared not do openly they attempted, however, to effect by the familiar method of indirection. It appears that while the plan to cut down the number of state sanitary supervisors in New York from twenty to ten was abandoned, the appropriations made allow only for ten of these important functionaries. If the next legislature does not make special provision for this need, the work of the New York state department will be seriously crippled.

It is gratifying to observe that Governor Whitman, in his address of welcome to the American Public Health Association at Rochester, on September 7, placed himself fairly on record against such petty politics. He said:

> I greatly regret that the legislature at its last session did not make appropriations adequate to fully maintain the work of certain divisions of the state department of health, especially the division of sanitary supervisors, whose work has proved most important and beneficial to the local communities, and by means of whom the knowledge and skill of the expert sanitarians of the department of health are placed at the disposal of the health officers of even the most remote rural districts. I sincerely hope that some means may be found by which the services of these physicians may be retained, and feel confident that next year, when the members of the legislature are made fully acquainted with the facts as to the value of these services, funds will be provided for their continuance. I shall use my influence to attain this end, for while rigid economy in the administration of the finances of the state is essential, savings in expenditure attained through decreased efficiency in health work are not only unwise, but resolve themselves, in the end, into irreparable waste of the most valuable resources of the commonwealth.

TRANSFUSION OF BLOOD

The recent review by Ottenberg and Libman[1] of 212 transfusions performed at Mount Sinai Hospital is a good index of the favor with which this form of therapy is being received. The most impressive part of this report deals with forty-two instances in which transfusion appears to have saved life; twenty-nine of the patients were discharged as well, while thirteen were saved from immediate death, although they continued to suffer from chronic ailments. While these and other results demonstrate that transfusion is no small factor in saving life, only a limited number of surgeons feel capable of doing transfusion with reasonable certainty of success. A brief consideration of the present status of the technic of transfusion, therefore, seems not untimely.

Current literature is so replete with papers on the subject that it is difficult to select a simple method for use. Blood transfusion was employed with reputed good results long before the advent of modern surgery. Recent interest, however, dates chiefly from Carrel's excellent work on the suture of blood vessels, and Crile's transfusion by means of metal cannulas.

Brewer and Leggett[2] first used paraffin-coated glass tubes for the conduction of the blood. Curtis and David[3] introduced the use of a large paraffin-coated glass bulb which permits accurate measurement and satisfactory transfer of blood from donor to recipient.

A similar device later invented by Kimpton and Brown[4] has been extensively used with gratifying results.

Lindeman[5] employs sets of ingenious trocar-cannulas to which syringes are attached. The use of salt solution aided by frequent change of syringes prevents clotting. Lindeman's method has met much favor in transfusion at Mount Sinai Hospital. Unger[6] recently evolved a modified syringe method which minimizes traumatism of the vessels and alternately washes out the vessels of the donor and recipient with salt solution.

To prevent clotting — a factor to be reckoned with in any method — Satterlee and Hooker[7] advocate herudin (leech venom), a substance which inhibits coagulation but seems not always devoid of toxic effects. It is not improbable that various preparations differ considerably in the amount of toxin contained. Sodium citrate solution, extensively employed by laboratory workers to prevent coagulation, has been warmly advocated by Weil,[8] and more recently by Lewisohn.[9] The evidence at hand in Lewisohn's report indicates that this solution, when diluted to a point at which it may be introduced freely into the circulation, is still capable of inhibiting coagulation. The most efficacious and generally satisfactory sodium-citrate-blood mixture is as yet unsettled, and perhaps varies according to the blood used; but citrate in a proportion not greater than 0.2 per cent. appears to be satisfactory. In this issue of THE JOURNAL, Simons[10] reports certain experiences which lead him to condemn the use of sodium citrate to prevent coagulation of the transfused blood, so that results of further observation will be required before the availability of the citrate method is determined.

In selecting a donor, two things must be guarded against: First, the transmission of disease, notably syphilis, must be avoided; second, the possibility of hemolysis and agglutination must be excluded. When urgency or lack of laboratory facilities demand, members of the immediate family offer the minimum risk. In all other instances, the Wassermann test and examination for hemolysis of the donor's blood by that of the recipient are necessary. For the latter, the recently described procedure of Rous and Turner[11] is commendable for its simplicity.

To summarize: One who is possessed of average surgical ability can learn to do transfusion; a good technic should be acquired by preliminary work on dogs before human transfusion is attempted. It must, moreover, be recognized that, although many devices now employed yield good results in practiced hands, painstaking care and accurate technic are always necessary. Among the devices which have been successfully used in large series of cases are the glass bulb of Curtis and David, the cylinder of Kimpton and Brown, and the syringe sets of Lindeman. The recent "modified syringe method" of Unger promises much. It would seem probable that eventually through the discovery of harmless anticoagulating methods, transfusion will become a simple procedure. In the meantime, there is no doubt that a more widespread attention on the part of surgeons to the mastery of a good technic of transfusion would be the means of saving many lives.

THE PROBLEM OF SECRETORY NERVES FOR THE THYROID

Evidence which has been presented in favor of the existence of true secretory nerves controlling the thyroid glands has already been reviewed in THE JOURNAL.[1] Among the latest investigators to follow the earlier lead of Asher of Berne, in adducing physiologic evidence supposed to support the view that the glands are under the domination of a nervous mechanism, are Beebe and his collaborators. They base their conclusion on the observation that prolonged stimulation of the thyroid nerves causes a slight reduction in the iodin content of these secretory structures.

It cannot be denied that a histologic basis for the views here referred to exists. Both the vessels and the cells of the thyroids are abundantly supplied with nerve fibers. Vasomotor impulses can readily find a nervous path to the gland. Such structural facts, however, do not conclusively demonstrate the functional necessity of these nervous accessories in the normal activities of the thyroids. There are, today, numerous available illustrations of glandular mechanisms well supplied with nervous structures which nevertheless receive their activating influences through the medium of the circulation. They are stimulated, we now say, by hormones.

Under certain conditions, thyroidal tissue may readily be transplanted to widely separated parts of the body, as, for example, the suprarenal, ovary, subperitoneal tissue, muscle, and subcutaneous fascia of the neck, chest and abdomen. If a sufficient amount of the main gland is removed, under appropriate conditions a compensatory hyperplasia of the remaining stump will ensue; and, in addition, a simultaneous and similar degree of hyperplasia of any transplants may occur independent of their location.

---

[1] The Nerve Control of the Thyroid Gland, editorial, THE JOURNAL A. M. A., July 25, 1914, p. 325.

When very small doses of some iodin-containing substance are given, whether by mouth or by cutaneous applications of tincture of iodin, for example, involution of the thyroidal tissue promptly ensues in from two to three weeks. The change affects the transplants, irrespective of their location, in the same way as the main thyroid stump is affected. These facts are due to the investigations of Manley and Marine[2] of the H. K. Cushing Laboratory of Experimental Medicine at the Western Reserve University in Cleveland. If iodin, which protects against thyroidal hyperplasia, is administered prior to or at the time of transplantation, no hyperplasia of either the original gland or transplants occurs until the effect of the iodin has fallen to the level of inducing an insufficiency. Likewise, if iodin is administered following transplantation, no hyperplasia ordinarily occurs during the time of such administration.

But this is not all. If a large part of the transplanted thyroid tissue and of the original gland, thus involuted, is removed, the *remaining transplants and the remaining portion of the stump undergo active hyperplasia for the second time.* In evidence of the fact that the transplanted thyroid tissue actually can function, Manley and Marine have observed marked amelioration of the symptoms of operative myxedema associated with active hyperplasia of subcutaneous abdominal transplants in animals.

When thyroid tissue can "take" and grow in widely different parts of the body, when the transplanted tissue can undergo hyperplasia simultaneously with the original stump and in a form histologically identical with it, when a drug like iodin can affect these surgically disconnected fragments in the same way and at the same time, an explanation of these phenomena based on a theory of nervous control does not appear to be tenable. The Cleveland investigators believe that the thyroid may function as a true blood-vascular gland in that the stimuli which cause these hyperplasias may reach the gland cells through the blood stream, and that influences causing thyroid involution may be transmitted by the same means.

It would be illogical, indeed, to draw the conclusion, from what has been said, that specific secretory fibers to the thyroid glands do not exist. The new observations just cited do not directly touch this question. They clearly demonstrate, however, as Manley and Marine point out, that secretory fibers are not essential in order that the thyroid tissue may exhibit the characteristic morphologic and physiologic changes known to be associated with great variations in functional activity.

ENGLISH AND GERMAN MEDICAL EDUCATION

On another page[1] we reproduce in abstract a recent article by Mr. Flexner on "The English Side of Medical Education." It is really a comparison of the English with the German system of medical education. It is evident that neither system should be copied in its entirety in the efforts made to develop medical education. In Germany the teaching of the laboratory sciences has reached perhaps its highest stage of development, and the method of selecting teachers for both laboratory and clinical departments is on the basis of scientific eminence. In these respects the German method would be more worthy of adoption in this country. According to Mr. Flexner, however, the German system of medical education is weak in that the lecture still constitutes the backbone of the instruction furnished and, in fact, is largely the bulk of the instruction. Again, in the medical course the student is still a mere onlooker and does not have free admission to the patients at the bedside. The German course, therefore, is excellent in the development of research workers, but the practical benefit is lost by the failure to allow the student to make use of the knowledge obtained in the laboratory departments in first-hand study and treatment of patients. From other sources meanwhile, it is evident that even during the required intern year his freedom in the hospital is seriously limited.

The weaknesses of the English system, on the contrary, correspond almost entirely to the points which are strong in the German system. In England secondary education has not been so thoroughly developed as in Germany; hence the student is not as well qualified to enter on the study of the so-called laboratory sciences. Meanwhile, these laboratory sciences, with the exception of physiology, are not well developed in the English medical school. Only elementary instruction in anatomy is provided for; pathology is taught only from the gross and descriptive points of view; modern pharmacology is almost unrecognized, and adequate provision for scientific research is almost entirely lacking. For this reason clinical teachers are rarely men of scientific vision or enthusiasm, and are unable to impart the spirit of scientific research to their students.

The method of appointing members of the faculty in England is at fault, since it depends on seniority. There is also considerable inbreeding. Younger men, usually recent graduates of the institution, are appointed to the lesser positions in the hospitals, and promotion depends not on productivity so much as on merely a faithful performance of routine duties. If they stay in the hospital, they are bound in time to reach the higher positions.

The strength of the English system lies in the fact that from the beginning the student has free access to the hospital, where, as a clinical clerk, he has free entry to the bedside of patients. This not only gives him his opportunity to observe facts of diagnosis and treatment, but also it is his duty to assist in the examination and care of patients. As Mr. Flexner says, "he observes his master at work; he is permitted to examine the patient, to confirm or to disprove his master's observations and, subject to his master's control, to go through all the motions involved in the practice of medicine." Cases are assigned to the students or clerks in rotation, each clerk being required to make a complete history and description of each of his cases, including the requisite microscopic examinations. "This method," says Mr. Flexner, "fulfils every requirement of sound teaching; the student is at first hand familiar with the patient; he is compelled to observe and to think; he notes and reports progress from day to day; he sees his master on trial as the procedure followed is either vindicated or discredited by the developments."

---

[2] Manley, O. T., and Marine, D.: Studies in Thyroid Transplantation, I, Data Relative to the Problem of Secretory Nerves, Proc. Soc. for Exper. Biol. and Med., 1915, xii, 202.

[1] The English Side of Medical Education, The Journal A. M. A., this issue, p. 1391.

It would seem, therefore, that for the highest development of medical education, the medical school should adopt the German method of selecting teachers on the basis of attainments and combine this with the clinical clerk system of hospital teaching as employed by the English schools. Of course, every college needs adequate funds for the employment of full-time teachers, for the adequate equipment of its laboratories, and for the development of medical research. The most useful medical school is not the one which merely passes on the theoretical medical knowledge of former generations, but the one which also, through research, adds to the knowledge of the etiology, diagnosis and treatment of diseases and, through its hospital, and the thoroughly trained physicians graduated each year, gives the public the benefit of this knowledge.

THE DISTRIBUTION OF THE BLOOD IN SHOCK

It almost requires courage to venture on any added discussion of the subject of shock. A multiplicity of more or less isolated facts pertaining to shock have been woven into the fabrics of belief of varied kinds. One of the incentives for increasing the variety and number of hypotheses in regard to shock lies in the eminently practical aspects of the problems that they encompass. A really tenable explanation of shock would find prompt service in the routine of the practitioner. The secretary of commerce recently remarked, in an address entitled "First Get the Facts,"[1] that "the truth of yesterday is not that of today. The truth of today is but the parent of that which is to be tomorrow. . . . Where prejudice is, truth is so far excluded, for no judgment given in advance of known truth is either sound or safe." Therefore it is essential in any progressive vocation that "the sight, whether it be far or near, shall know a fact when it sees it and be ready to abandon a pseudo fact for a real one and to abide by the latter till further facts are found."

The foregoing must serve as the excuse, if such is needed, for reverting to new facts in regard to the distribution of the blood in shock. It is evidently the disturbance in the normal distribution of the circulating fluid of the body that constitutes an essential factor in shock. Janeway and Jackson[2] of the University and Bellevue Hospital Medical College, New York, have adopted for their experimental studies that form of shock which is produced by mechanical means, because, under these conditions, fewer extraneous factors enter into the consequences of the primary disturbance of the normal distribution of the blood. It consists in a controllable partial occlusion of the vena cava inferior in the chest, whereby the amount of blood passing from the veins to the arterial side of the circulation can be accurately controlled, and, in consequence, the blood pressure regulated. The observations made in this way on the altered volume of various visceral organs as the result of induced changes in the blood supply lend emphasis to the importance of what Yandell Henderson has described as the venopressor mechanism, and they confirm its failure in shock.[3]

Through the inability of the blood in the inferior vena cava to discharge adequately into the heart, there results a mechanical distention and increased intravascular pressure in the capillaries and small venules of the regions draining into this vessel. After release of the experimental obstruction, the arterial pressure, which has previously been low, may return for a time to a comparatively high level. According to Janeway and Jackson, the crucial factor concerns a progressive fall in the arterial pressure: after the relief of the obstruction to the flow through the inferior vena cava, there occurs, even after a more or less complete restoration of the arterial blood pressure, a progressive fall until death. This, they assert, can be the consequence only of some change in the walls of the vessels primarily affected by the occlusion of the inferior vena cava, namely, the capillaries and small venules. On this basis, then, in mechanically induced shock, a mechanical distention of a certain degree and persistence is liable to cause an alteration in some normal property of the capillaries — of their tone — as the result of which they lose the power of emptying the increased quantity of contained blood through the heart into the arterial side of the circulation. This power is retained, however, after shorter periods of overdistention or distention of lesser degree.

---

[1] Redfield, W. C.: First Get the Facts, Science, July 9, 1915, p. 39.

[2] Janeway, H. H., and Jackson, H. C.: The Distribution of the Blood in Shock, Proc. Soc. Exper. Biol. and Med., 1915, xii, 193.

[3] Some Conditions Inducing Excessive Respiration, editorial, The Journal A. M. A., June 13, 1914, p. 1897; The Vasomotor Center in Shock, Current Comment, May 8, 1915, p. 1588.

Overdistention of the capillaries may result in various ways: By obstruction to the venous return to the heart there may be a draining back of blood within the capillaries, or in other forms of shock there may be sudden discharge of blood at high pressure into the capillaries. It seems to be a fact that in any case the normal quota on the arterial side of the circulation is diminished. Even after the original cause of the disturbed distribution of the blood, whether mechanical, toxic or inhibitory in nature, is removed, the circulatory condition may persist; and in fatal cases the abnormal diminution of the blood apparently progresses from local peripheral causes alone until death occurs. Janeway and Jackson express the abnormality by saying that shock consists in a general displacement of what may be termed a critical quantity of blood from the arterial to the capillary and venous side of the circulation, a displacement which is therefore accompanied by comparatively insignificant volumetric changes, and dependent largely on a loss of existing tone in the walls of the small venules and capillaries.

THE SOY BEAN, ITS ENZYMES AND CARBOHYDRATES

The soy bean (*Glycine hispida*) is an annual leguminous plant, a native of southeastern Asia. In Japan and China, where it has been grown from time immemorial, it is used for human food and is an important crop in many provinces.[1] Over two hundred varieties of the bean are reported, and many and varied kinds of food are made from it. Though known in Europe since the latter part of the eighteenth century, and in the United States since 1829, it long remained a botanic curiosity in both places. It was introduced into the United States on the return of the Perry expedition from Japan in 1853. For more than twenty-five years it has been under investigation by the U. S. Department of Agriculture and by some of the state agricultural departments, and is just now beginning to take a place as a farm crop. The North Carolina Experiment Station recommends soy beans as a palatable vegetable, but their use has not become general; they are used in this country chiefly as forage plants, for ensilage and to enrich the soil.

Recently the soy bean has achieved some degree of medical prominence because of two characteristics: It contains several enzymes, one of which, urease, decomposes urea into ammonia and carbon dioxid. This enzyme is therefore used to determine the amount of urea in the urine, the blood and other body fluids.[2] Also, being very rich in protein and fat and containing only traces of starch, soy bean products have been recommended as foods for diabetics.[3] In combination with condensed milk and barley flour, their use has been advised in the form of a gruel for infant feeding in cases in which fresh milk cannot be obtained or the milk supply is questionable. They have been recommended in certain cases of inability to digest cow's milk and of temporary intestinal derangement.[4]

Although the soy bean is almost completely free from starch, it contains about 20 or 25 per cent. of nitrogen-free extract (total carbohydrates) which, until recently, had not been thoroughly studied. Since starch is not the only carbohydrate injurious to diabetics, it is desirable that the identity, amounts and percentages of the various carbohydrates in the bean should be worked out. Street and Bailey[5] of the analytical laboratory of the Connecticut Experiment Station, present analyses of several varieties of soy beans which have been grown on the experiment station farm. The average percentages are: water 10, ash 5.54, protein 38.29, fiber 4.64, nitrogen-free extract (total carbohydrates) 26.64 and fat 14.89. The average percentages from similar analyses of several commercial soy bean flours are: water 5.1, ash 4.5, protein 42.5, fiber 3.7, nitrogen-free extract 24.3 and fat 19.9. The greater proportion of protein and fat in the commercial flour is attributed by Street and Bailey to loss of the other ingredients through bolting and other purifying manufacturing processes. The constituents of the nitrogen-free extract were especially studied for a single variety of the beans grown on the experiment station farm. The results in percentage are: total sugars 4.51, starch 0.50, dextrin 3.14, pentosan 4.94, galactan 4.86 (less 0.24 due to raffinose), cellulose 3.29, organic acids 1.44 and waxes, color principles, etc., 8.60. Street and Bailey remark that, of these constituents, only the first three—the sugars, starch and dextrin—amounting to 8.15 per cent., may be considered objectionable in a strict diabetic diet. "The remaining nitrogen-free extract, 22.93 per cent., about three fourths of the whole, consists of . . . forms which are not generally considered a source of danger in a diabetic diet."

These investigators also studied the enzymes of the soy bean, finding a protease of the peptoclastic type, a peroxidase and a lipase in addition to the urease, amylase and glucosid-splitting enzyme previously reported. Sucrase and protease of the peptonizing type were not found. Owing to the wide distribution of enzymes in vegetable tissues and the ease with which they can usually be detected, less importance is attached by the authors to this section of their report.

[1] Piper, C. V., and Nielsen, H. T.: Soy Beans, Farmer's Bull, 372, U. S. Dept. Agric., 1909. Ball, Carleton R.: Soy Bean Varieties, Bur. Plant Ind. 98, U. S. Dept. Agric., 1907.

[2] Two urease preparations (arlco-urease and urease-Dunning) have been admitted into New and Nonofficial Remedies (N. N. R., 1915, p. 362).

[3] See for instance Friedenwald and Ruhräh (The Use of the Soy Bean as a Food in Diabetes, Am. Jour. Med. Sc., December, 1910, p. 793). Diabetic foods (hepco flour, hepco dodgers, and hepco grits) made from the soy bean have been admitted into New and Nonofficial Remedies (N. N. R., 1915, p. 193).

[4] Ruhräh, John: The Soy Bean and Condensed Milk in Infant Feeding, Am. Jour. Med. Sc., October, 1915, p. 502.

[5] Street, J. P., and Bailey, E. M.: The Carbohydrates and the Enzymes of the Soy Bean, Jour. Indust. and Engin. Chem., October 1915, p. 853.

The chief interest of their work naturally centers in the carbohydrate analyses.

An interesting point is the suggestion that differences in starch content of the beans found by various investigators are probably due to differences in ripeness, or rather to differences in the circumstances under which they are allowed to ripen. "Harz found that, when the beans do not ripen thoroughly, or when they are allowed to ripen after the vines are cut, starch may be present, certain varieties being more likely to contain it than others, whereas if the beans are thoroughly ripened they are practically free from starch." In this connection it should be noted that Street and Bailey do not state whether or not the beans which they analyzed were hulled. Ruhräh[4] lays stress on the importance of the removal of the skins or "coarse fibrous hulls which contain little protein in the preparation of soy beans for diabetic or infant food." In any case, it is satisfactory to know that the total amount of sugar-forming carbohydrates contained in soy beans falls well within the limit of 10 per cent. regarded as safe for diabetics.

Current Comment

"AT THE BAR OF PUBLIC OPINION"

When the medical profession gives the public facts regarding the fraudulence and dangers connected with the exploitation of "patent medicines," the "patent medicine" manufacturer has a stock retort ever ready: "The doctors are opposed to 'patent medicine' because it hurts their business; because 'patent medicines' cut into the income of the medical profession." Few excuses ever rested on a less substantial basis. Considered from the financial standpoint only, the fraudulent "patent medicine" business is the physician's greatest boon. Far from curtailing his income, the advertising and selling of fraudulent "patent medicines" greatly augment it. Every lurid "patent medicine" advertisement that frightens the healthy into the belief that they are ill sends four of such people to the doctor to one that it sends to the "patent medicine" counter. No small proportion of the physicians' patients are those who, neglectful of disease in its early stages, and believing the claims made for fraudulent "patent medicines," have placed their dependence on these products until they have reached a condition where prolonged medical attention is imperative. For years most newspapers and many magazines have been under the blighting influence of the profits of quackery. But a change is taking place and many newspapers and magazines of the better class are now outspoken in their denunciation of the cruelty and fraud that seem to be inseparable from the exploitation of "patent medicines." The Propaganda department of The Journal has collected some editorial opinions on the "patent medicine" business and quackery from newspapers and magazines and reprinted them in pamphlet form.[1] These editorial excerpts are from publications that not only have no possible connection with the medical profession but could, if they would, be beneficiaries of the "patent medicine" industry: they are criticisms of a business that, as the price of silence, would willingly give fat advertising contracts to the publications that have voiced them.

AMINO-ACIDS AND TUMOR TISSUE

The importance of certain amino-acids for the functions of growth has been emphasized by the recent work of Osborne and Mendel[2] and other investigators. When the proteins furnished in the diet are deficient in the amino-acids lysin and tryptophan, for example, growth is halted. These derivatives evidently cannot be synthesized by the animal organism; so that when they are lacking the protein structure of newly formed tissues cannot be built up. When the missing amino-acids are supplied either as such or in the form of proteins yielding them, youthful tissues can resume their growth. In contrast with normal tissues, malignant tumors are characterized by an exceptional tendency to grow. This fact, in connection with the features cited above, has raised the question whether or not these pathologic tissues show any unique composition with respect to the amino-acid "building stones" which enter into them. The chemical analyses of tumor tissue recorded up to date have been all but encouraging so far as any light thrown on the tumor problem is concerned. They have been fragmentary and inadequate in respect to both methods and results. There are, however, a few amino-acids which can be estimated at the present time with some approach to accuracy. The list includes arginin, histidin and lysin. This has encouraged Kocher to attempt a new comparison of the content of normal somatic and tumor tissue of man in respect to the amino-acids just mentioned.[3] Their quantity was found in five cases of malignant neoplasm to be approximately double that found in normal tissue. Whether such high percentages of these important amino-acids is a peculiarity of tumors or whether a corresponding increase will be found in normal rapidly growing tissue is a problem now under investigation. Kocher believes, however, that his results suggest a new approach to the study of the cancer problem, especially as it relates to metabolism. He recalls the evidence offered by Sweet, Rous and others[4] that when white rats having carcinoma are fed on a diet deficient in these basic amino-acids the tendency to metastasize is frequently diminished. Sometimes the tumors grow rapidly in these experimental cases, but there is a correspondingly rapid emaciation of the body. This fact, says Kocher, may indicate that the somatic tissue in such instances is broken down to furnish the required amino-acid to the rapidly growing tumor cells.

THE SELECTIVE ACTIVITY OF THE KIDNEY

A comparison of the composition of the urine from each of the two kidneys after damage to one of them might be expected to reveal evidence regarding the possible selective power of the renal cells in relation to waste products. The modern blood analysis has already furnished facts to indicate that under pathologic conditions the kidneys may not be equally "permeable" or "impermeable" to all of the usual urinary components. Accordingly the "retention" of one or another of the familiar excretory products is announced and the expressions "salt retention," "nitrogen retention," etc. have come into use. They are indicative, without being conclusive, of a possible specific functional deterioration of the kidneys. Folin and Denis[1] have obtained complete and simultaneous collections of urine from each kidney, for reasonably long periods, after damage to one of these organs. The patients had been operated on for malignant growths in the bladder, so that a double ureterostomy rendered possible the collection of "single kidney" urines. In each case one or both kidneys had been infected and in addition somewhat damaged by the pressure of the bladder tumor on the ureteral opening. The hydronephrosis resulting from such back pressure is currently believed to injure the convoluted tubules rather than the glomeruli. The comparative analyses of a limited number of cases show that the damage produced by moderate hydronephrosis complicated by pyelitis is not particularly uniform in character so far as the excretory power of the kidneys is concerned. Comparisons of chlorid and nitrogenous excretion show that the capacity to eliminate nitrogenous substances is more easily or more frequently damaged than is the salt excretion. Indications of more detailed selective injury are seen in the lack of correspondence between the variations in phosphate and chlorid excretion. The output of creatinin and uric acid likewise did not vary together. A new conception is indicated by these unique clinical experiments. Without generalizing too minutely on the basis of the still limited data, Folin and Denis believe that their figures agree with the view that the excretion of urine by the kidney can be subdivided into an unknown number of more or less independent excretions. This is in harmony with other established physiologic facts regarding renal excretion.

MUSCULAR TISSUE IN THE AURICULOVENTRICULAR VALVES

Stanley Kent[2] has recently described muscular tissue, in the valve segments of the hearts of mammals, where its existence has hitherto apparently not been generally recognized. The muscle is striated, of a character similar to that forming the walls of the heart's chambers, and is continuous with the contractile tissue of the auricular wall. The muscular tissue may penetrate the valve flap to a considerable distance, and there is reason to suppose that this valvular muscle contracts in sympathy with the auricle and as a direct result of impulses derived from it. It is likely, as Kent suggests, that muscle in the situation described and with the connections referred to may exercise an important function in connection with the closure of the auriculoventricular valves of the heart.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST; SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ALABAMA

Sanatorium Act Repealed.—The act of 1911 establishing a state sanatorium for tuberculosis has been repealed by the senate. The original act appropriated $40,000 for this purpose, and of this, $16,000 was spent for the purchase of a site in Cullman County, but the property has never been improved and no step has been taken for the erection of a building.

Plague Bill Passed.—The bill introduced by Senator Hartwell carrying a conditional appropriation of $10,000 to prevent the introduction of bubonic plague into Alabama through the port of Mobile or through any other avenue, has been passed by the senate by a vote of 13 to 8. It was explained that the funds are to be made available, if necessary, and in that case are to be handled by the State Board of Health with the approval of the governor.

Personal.—Drs. J. Alston Maxwell and Herbert Patton have been appointed surgeons for the student body of the University of Alabama, Tuscaloosa.——Dr. Tucker H. Frazer has been appointed dean of the Mobile School of Medicine of the University of Alabama, succeeding Dr. Eugene D. Bondurant, resigned, on account of ill health.——Dr. William M. Hestle, Buena Vista, was operated on recently in Baltimore for the removal of a growth from the lip, and has returned home.——Dr. Benjamin J. Baldwin, Montgomery, lost $5,000 as the result of a fire which destroyed his buildings, September 30.

CALIFORNIA

Health Department Moves.—The health department of Los Angeles has moved its headquarters from the City Hall to the Normal Hill Center.

Refuse to Rescind Isolation Regulation.—The board of supervisors of San Francisco, by a vote of 15 to 1, turned down the petition of the Parents' Rights League to take action to nullify the power of the local health board to isolate diphtheria carriers.

Prevention of Blindness.—The Jones bill for the prevention of blindness was passed by the legislature and became a law in June, 1915. The act gives the definition of ophthalmia neonatorum, requires that cases of this disease shall be reported within twenty-four hours, and provides that certain measures of prevention shall be taken by the local health officer and the State Board of Health. The new vital statistics law provides in the birth certificate a query whether the prophylactic for ophthalmia neonatorum was used.

GEORGIA

Prison Hospital Opened.—The hospital annex to the Federal Penitentiary, Atlanta, was opened September 29. The institution will accommodate 150 patients, and will be in charge of the surgeon-in-chief, assisted by professional men who are serving sentences in the Federal Penitentiary.

Urologists and Dermatologists Organize.—The Atlanta Urological and Dermatological Society was organized September 9, with an initial membership of twelve. Dr. Bernard Wolff was elected president; Dr. William L. Champion, vice president, and Dr. Omer F. Elder, secretary-treasurer.

Home for Crippled Children Opened.—The Home for Crippled Children established by the Scottish Rite Masons of

[2] Kent, A. F. S.: Illustrations of Muscular Tissue in the Auriculo-Ventricular Valves of the Mammal's Heart, Proc. Physiol. Soc., Jour. Physiol., 1915, xlix, p. xxxix.

Atlanta was formally opened, September 23, with fourteen inmates. The institution has two cottages in charge of a physician and nurse. The home is capable of accommodating twenty patients.

Medical Society Organized.—At a meeting of the physicians of Marion County held at Buena Vista recently, the Marion County Medical Association was organized with the following officers: president, Dr. Wesley Jefferson, Buena Vista; vice president, Dr. S. A. Murray, Tazewell; and secretary-treasurer, Dr. A. H. Drane, Buena Vista.

Personal.—Dr. and Mrs. Dean F. Winn, Atlanta, have returned from Russia. Dr. Winn was given the rank of lieutenant colonel in the Russian service on account of work done in the American Red Cross Hospital at Kiev.——Dr. Mather M. McCord, Rome, has been elected health commissioner of Floyd County and will assume office in January.——Drs. William P. Harbin and James C. Watts have been elected members of the board of trustees for the General Hospital to be established by Rome and Floyd County.

State Medical College Scholarships.—Scholarships in the medical department of the University of Georgia, Augusta, have been awarded by Governor Harris to the following applicants subject to the required examination: First district, S. H. Titshaw, Lyons; second district, R. W. Wimberly, Fort Gaines, and W. J. Ford, Sylvester; fourth district, Dr. W. E. Thomason, Texas; R. T. Park, Newnan, and Lee Reeves, Carrollton; eighth district, Jones Weems, Eaton, and Lamar Craft, Elberton; ninth district, Hoke S. Cantrell, Cornelia, and H. C. Chilson, Alpharetta; eleventh district, Lamar Harris, Wrightsville.

ILLINOIS

State Hospital Staffs to Meet at Elgin.—The State Hospitals' Medical Association of the State Hospitals of Illinois announces that its next meeting will be held at the Elgin State Hospital, October 28 and 29.

Personal.—Dr. George A. Zeller, Springfield, has been appointed alienist of the State Board of Administration.——Dr. and Mrs. Frederick E. Tulley, Granite City, have returned after a summer spent on the Pacific Coast.—Dr. William H. Maley, Galesburg, was painfully injured by the overturning of his automobile south of Maquon, October 3.

Joliet Hospital Must Enlarge.—The Will County Medical Society gave a dinner, September 23, in honor of the board of directors of the Silver Cross Hospital, Joliet, at which Dr. Frederick W. Werner presided. A maternity wing is urgently needed for the hospital, and plans have been made and approved for this addition. It was shown that the hospital had on hand about $30,000 to apply on the building fund. This leaves $45,000 to be secured in addition, and a committee was appointed to take up this matter.

Charity Conference.—The twentieth State Conference of Charities and Correction will be held in Danville, October 23 to 26, under the presidency of Dr. George T. Palmer, Springfield. The first day of the conference will be devoted to public health, nursing, visiting nurses, antituberculosis, etc., under the auspices of the Illinois Association for the Prevention of Tuberculosis.——The Illinois Association of County Home Superintendents and Illinois Probation Officers Association will hold their annual sessions in Danville, October 22 and 23.

Chicago

To Raise Money for Hospital in China.—Dr. Hie Ding Lin, an intern at Mary Thompson Hospital, made an appeal before the Women's Association of Commerce, September 30, to raise money for a free hospital for women and children at Foo Chow, China.

Tuberculosis Society Meeting.—The sixteenth meeting of the Robert Koch Society for the Study of Tuberculosis will be held at noon, October 18, at the City Club. On this occasion Dr. Francis M. Pottenger, Monrovia, Calif., will speak on "The Diagnosis of Tuberculosis by Palpation."

Physician's Wife Dies.—The sympathy of the members of the medical profession of Chicago goes out to Dr. Robert B. Preble in the sad affliction that has fallen on him. On October 6, through a fire that started in his house, Mrs. Preble and her mother were burned so that the latter died immediately and the former within a few hours.

Personal.—Dr. G. French S. Cary was severely injured last month while on a motor trip with his wife and baby near McCool, Ind., when the car went over a bank into a pool of water 18 feet deep.——Dr. and Mrs. Charles Adams have returned to Chicago after an absence of two years in Hawaii, the West Indies and Central America.——Dr. Reinhard Rembe is reported to have been decorated with the Iron Cross by the German emperor. Dr. Rembe has been in service with the German army since the outbreak of the war.——Dr. and Mrs. Arnold C. Klebbs, Switzerland, will spend the winter in Washington, D. C.——Dr. William S. White was operated on at the Evanston Hospital, October 8, for appendicitis and the removal of gallstones, and is reported to be improving.

MARYLAND

Typhoid in Baltimore.—During September, 189 new cases of typhoid fever were reported, with twenty-two deaths. During September, 1914, 130 cases occurred.

The Fight Against Malaria.—Senior Surg. Henry R. Carter, U. S. P. H. S., in charge of the Marine Hospital at Baltimore, has been detailed by Surgeon-General Blue to cooperate with the State Board of Health in stamping out malaria in Virginia.

Suits Decided in Favor of Physician.—Suits aggregating $15,000, brought against Dr. Alexander E. Muse, in which damages were claimed for injuries alleged to have been sustained by a 3-year-old boy who was struck by an automobile belonging to Dr. Muse, were decided in favor of the physician, October 1, as the fact was established that the automobile was being driven by a colored man without permission from Dr. Muse.

Physicians Form Civic Club.—At a meeting of physicians recently held at the Medical Library, a movement was started for the organizing of the Physicians' Civic Club, the object being to familiarize physicians with the city government and other subjects of interest to them. Dr. William T. Watson was elected temporary chairman and Dr. Frederic V. Bietler temporary secretary. The chairman was authorized to appoint a committee to draft a constitution and by-laws and another to nominate officers.

Personal.—Dr. William F. Lockwood, formerly dean of the College of Physicians and Surgeons, has been chosen dean of the School of Medicine of the University of Maryland to fill the vacancy caused by the death of Dr. R. Dorsey Coale. Dr. Lockwood is professor of medicine in the university and is a graduate of that school. Dr. Arthur M. Shipley, Baltimore, who has been acting dean since Dr. Coale's death, refused the deanship.——Dr. B. Merrill Hopkinson, professor of oral hygiene in the University of Maryland, delivered the introductory address to the students of the several classes, October 4.——Dr. John D. Blake, commissioner of health, has announced the appointment of Dr. William Travis Howard, Jr., as assistant commissioner, in place of Dr. C. Hampson Jones, Baltimore, and Dr. Austin H. Wood as secretary to the department.——Dr. Nathan R. Gorter, former health commissioner of Baltimore, has qualified as a member of the State Board of Health, to which he was appointed by the governor soon after his successor as health commissioner was named by the mayor.——Dr. Mary R. Fleming, a medical missionary of the Presbyterian Church, has arrived at Tabriz, Persia. She is a graduate of the Johns Hopkins Medical School, and at Tabriz will be physician and surgeon in charge of the hospital for women.

MASSACHUSETTS

Must Not Wrap Food in Newspapers.—Dr. Francis X. Mahoney, health commissioner of Boston, has issued an order to storekeepers prohibiting the use of unclean wrappers for food.

Ether Day.—The sixty-ninth anniversary of Ether Day was celebrated at the Massachusetts General Hospital, October 16. The exercises were held in the lower amphitheater in the outpatient department, and Dr. William Williams Keen, Philadelphia, delivered the address.

Course in Medicine and Pathology.—A course in medicine and pathology is to be given during October and November in the Pathological Amphitheater of the Massachusetts General Hospital by Dr. William H. Smith, visiting physician, and Dr. Oscar Richardson, assistant pathologist of the institution. The course will be given on Wednesday from 3:15 to 5:15 p. m.; is open to graduates of medicine and to third and fourth year students.

Personal.—Dr. Michael F. Fallon, Worcester, has been appointed a member of the Board of Registration in Medicine.——Dr. Alura A. C. Hughes, Boston, has been appointed medical inspector in charge of the nurses in the child hygiene division of the health department.——Dr. Benjamin H. Metcalf, Winthrop, has recently completed a tour by automobile to the Pacific Coast and return, a continuous journey of about 10,000 miles.——Dr. Edward C. Briggs, Boston, has resigned as professor of materia medica and therapeutics in Harvard Medical School and has been made professor emeritus.

MICHIGAN

Higher Entrance Requirements.—An official report states that beginning in the fall of 1916 the entrance requirements of the University of Michigan, Homeopathic Medical School, will be raised to two years of collegiate work. This makes forty-six medical colleges which in 1916 will have put into effect for admission the requirement of two or more years of collegiate work.

Personal.—Dr. Marinus L. Holm, Lansing, formerly state bacteriologist, but recently placed in charge of the branch laboratory of the State Board of Health at Houghton, has resigned and will practice in Lansing.——Dr. Albert F. Stone, Bay City, injured his left hand in the gear of his automobile September 30, necessitating the amputation of the first and third fingers.——Dr. Christopher G. Parnall, Jackson, has been appointed district medical inspector for Jackson and Lanawee County.——Dr. Arthur E. Ames, Morrice, was seriously injured by the overturning of his car in a collision with another automobile recently.——Dr. Morton Gallagher, Bay City, is reported to be seriously ill following an attack of sciatica.

MINNESOTA

New Medical Building.—The new twelve-story building to be erected on Seventh Street, Minneapolis, for the use of physicians at a cost of more than $300,000, is to be commenced this month.

Emergency Ambulance Service.—An emergency ambulance association is being formed among the physicians of Duluth. The object of the organization is to place in service an automobile ambulance. Dr. William A. Coventry, Duluth, is in charge of the project.

Hospital Notes.—Dr. Giles R. Pease, Redwood Falls, expects to open his new hospital in that city this month.——Dr. Fletcher W. Powers has added a two-story porch and sun parlor to his hospital building in Barrett and has renovated the entire building.

New State Officials.—At the annual meeting of the Minnesota State Medical Association in Rochester, September 29 to October 1, the following officers were elected: president, Dr. J. Warren Little, Minneapolis; vice presidents, Drs. John J. Donovan, Litchfield; Arthur C. Rogers, Faribault, and Charles O. Wright, Luverne; secretary, Dr. Thomas S. McDavitt, St. Paul (reelected); treasurer, Dr. Earle R. Hare, Minneapolis; and councilors, Drs. Richard J. Hill, Minneapolis, fourth district, and Franklin A. Dodge, LeSueur, seventh district.

Personal.—Dr. William A. Bessesen, Albert Lea, suffered a loss of $4,000 in the destruction of his building by fire, September 28.——Drs. Herman W. Froehlich, Harvey G. Hieber, Francis Gambell, Jesse E. Douglass and Oscar F. Mellby, Thief River Falls, were the guests of honor at a dinner given by the local commercial club, September 24, as an appreciation of the work done by the physicians in establishing the new hospital at Thief River Falls.——Dr. Andrien J. Kirghis, St. Cloud, has started for France and expects to enter the French medical service.

MISSOURI

St. Louis

Personal.—Dr. Frederick Hagler has returned from abroad where he has spent several months in the service of the Red Cross.

Reduction of Feebleminded in Schools.—Dr. J. E. Wallace Wallin, director of the psycho-educational clinic of the St. Louis public schools, in his first annual report, shows a decrease of nearly 25 per cent. in the number of children listed as feebleminded, as compared with last year. When Dr. Wallin took charge of the clinic, 468 pupils were receiving instruction in special schools for the feebleminded. By classifying these children he has reduced the number of pupils in special schools to 372. Of the total number of children examined by him, 7 per cent. proved normal; 12 per cent. showed evidence of retarded intellect; 33 per cent. were listed as backward; 11 per cent. were on the borderline between backwardness and the first state of feeblemindedness; 15 per cent. were morons; 14 per cent. imbeciles, and 1 per cent. idiots. Of the entire number, 20 per cent. had speech defects.

MONTANA

School Inspection.—The members of the Gallatin County Medical Society have again secured the inspection of the Baker Creek school district. This is the only rural school in the state under inspection.

Personal.—Dr. Edward M. Gans has been elected mayor and president of the Commercial Club of Judith Gap.——Drs. James F. Blair and Joseph H. Delaney, Bozeman, toured Yellowstone Park by automobile during September.——Dr. James F. Blair, Bozeman, has gone east for postgraduate work and the surgical congress.——Dr. Herbert H. Judd, Bozeman, spent his vacation in an automobile tour of Glazier Park.——Dr. William C. Riddell, Helena, was in charge of the safety and health committee of the Montana State Fair, which was visited by 40,000 persons during the week.

NEW YORK

Personal.—Dr. Otto R. Eichel has been appointed by Dr. Biggs to the position of director of the division of sanitary supervisors of the State Department of Health.

Harvey Society Lectures.—The first lecture of the eleventh course of the Harvey Society will be delivered at the New York Academy of Medicine on October 16 at 8:30. At this time Prof. C. W. Stiles of the Hygienic Laboratory, Washington, D. C., will lecture on "Recent Studies on Schoolchildren with Special References to Hookworm Disease and Sanitation."

New York City

New Buildings for Randall's Island.—The aldermen have voted $650,000 in corporate stock for new buildings for the children's hospital and schools on Randall's Island and for the nurses' home on Blackwell's Island.

Pensions for Widowed Mothers.—The Board of Child Welfare which is to administer the Widowed Mothers' Pension Law has for the first time presented its budget for this city, and the board will ask $483,000 for the relief of widowed mothers and $36,000 for office expenses. Applications are in from 3,166 mothers who are estimated to have 9,204 children. These figures do not include 1,500 children who are now in institutions who might be returned to their mothers. Each case is to be investigated and passed on before 1916.

Health Department Will Aid in Diagnosis of Glanders.—The health department announces that it is prepared to test, free of cost, by the blood reaction for glanders, all horses in the greater city of New York. Horse owners are urged to take advantage of this facility by employing a competent veterinarian to collect a specimen of blood from each horse in their stable and to forward it to the department together with the number which is issued to the horse by the department of agriculture of the state. The department intends to have all horses in the city tested. If an owner indicates that he cannot have a specimen for examination collected by a private veterinarian the department will consider a request to have it done by a veterinarian in the employ of the city.

Physical Examination of Schoolchildren by Private Physicians.—The attention of all the physicians in the city has been called to that section of the sanitary code and to the regulations governing the physical examination of schoolchildren of the city of New York. It is the desire of the department of health to have all schoolchildren physically examined by their private physicians and to have the medical inspectors assigned to duty in the schools examine only those children whose parents are unable to afford the services of a private physician. The department announces that it counts on the cooperation of the medical profession and that prompt examination with the immediate return of the card, properly filled out, will greately facilitate the work of the Bureau of Child Hygiene. A copy of the card form together with the regulations of the board of health with respect to this examination is being sent to all physicians in the city.

The Interstate Commission to Fight Mosquitoes in 1916.—In order to avoid a repetition of this year's mosquito experience, Commissioner Goldwater proposes the formation of an interstate commission to fight mosquitoes in 1916. New York City was not alone in its suffering from mosquitoes during the past summer; the situation was no better in the neighboring states. The residents of the nearby states have a common interest in this matter with those of New York City. Furthermore, no permanent relief from the nuisance can be expected by New York, unless vigorous preventive measures are simultaneously prosecuted in Connecticut, New Jersey and Westchester County. For these reasons the formation of an interstate commission is proposed. It will be organized if Dr. Goldwater's plans are carried out at the end of this year. The U. S. Public Health Service has been invited to join and has been requested to nominate a chairman to direct the work of the commission.

OHIO

Portrait of Dr. Conner Presented.—An oil painting of the late Dr. Phineas S. Conner was presented to the Cincinnati General Hospital by Dr. Charles E. Caldwell, September 14.

Hospital Dedicated.—The Good Samaritan Hospital, recently completed at Clifton and Dyxsmith Avenue, Cincinnati, was dedicated with appropriate ceremonies, October 2. The buildings and equipment have cost thus far about $175,000, only one wing of the institution being completed. The plans call for a five-wing edifice, which will cost more than $300,000. The addresses on the occasion were delivered by Dr. Charles L. Bonifield, Cincinnati; Dr. Henry T. Sutton, Zanesville, a member of the State Board of Health, and Dr. Lewis S. McMurtry, Louisville, Ky.

Personal.—Dr. Philip D. Wilson, Columbus, has returned after a term of military hospital service in France.——Dr. John R. Johnson, for more than two and a half years superintendent of the district tuberculosis hospital at Lima, resigned, the resignation taking effect October 15. After a postgraduate course in New York City, he expects to return to Lima and enter practice.——Dr. Roger S. Morris has been appointed full-time professor on the staff of the Cincinnati General Hospital.——Dr. Rufus A. Van Voast, Cincinnati, has returned home after several months' hospital service with the French army.

Work on New Medical School Begins.—Dr. Christian R. Holmes, Cincinnati, announced September 27, that the work of grading the ground for the new medical school directly opposite the contagious group of buildings of the Cincinnati General Hospital had begun. The school will be ready for occupancy in about a year and a half. The cost of the buildings will be about half a million dollars and the institution will have accommodations for about 200 students.

Saturday Evening Free Lectures.—The following is the program of the Saturday evening free lectures before the B. Merrill Ricketts Experimental Surgical Research Laboratory for the season 1915-1916:

October 16—Dr. Mortimer Frank, Chicago. The History of Glands. (Illustrated.)

October 23—Dr. Frank Winders, Columbus. The Heart Comparative Anatomy. Function, Uses and Abuses. (Illustrated.)

October 30—Dr. Sydney E. McKee, Cincinnati. Two Years' Travel Around the World. Medical and Scenic. (Illustrated.)

November 6—Dr. Axel F. Werelius, Chicago. Surgery of the Heart, Lungs and Trachea. (Illustrated.)

November 13—Dr. Chas. T. Souther, Cincinnati. The Stomach Comparative Anatomy, Function and Surgical Aspects. (Illustrated.)

November 20—Dr. DeEnna D. DeNeen, Cincinnati. The Ureter Anatomy, Function and Restoration. (Illustrated.)

November 27—Dr. David I. Wolfstein, Cincinnati. The Cerebellum and Its Function. (Illustrated.)

December 4—Dr. Wm. E. Schenck, Cincinnati. Optical Instruments Construction and Uses. (Illustrated.)

December 11—Dr. William J. Thomasson, Newport, Ky. The Upper Air Passages and Tonsils. Comparative Anatomy and Diseases. (Illustrated.)

December 18—Dr. Sparrell S. Gale, Roanoke, Va., Chief Surg. N. & W. R. R. Safety First, How It Saves Life and Property. (Demonstrations.)

January 8—Prof. Chas T. P. Fennel, Cincinnati. Poisons and Narcotics (Mineral, Vegetable, Animal and Insect). (Illustrated.)

January 15—Dr. Willard D. Haines, Cincinnati. Cancer of the Stomach, Precancerous Condition and Surgical Aspects. (Illustrated.)

January 22—Dr. Joseph E. Pirrung, Cincinnati. Hare Lip and Cleft Palate. Their Embryology, Causes and Correction. (Illustrated.)

January 29—Dr. Chas. F. Hicks, Welch, W. Va. Six Hundred Gun Shot Wounds in Mining Practice. Conclusions. (Illustration of Muscles.)

February 5—Dr. Frank Warner, Columbus. A Study of the Relationship of Arteriosclerosis to Malignancy. (Illustrated.)

February 12—Dr. Wm. M. Doughty, Cincinnati, and Mr. J. R. Kelley (Kelley-Koett). The Roentgen Ray, Its Use and Abuse, Demonstratious and Development of Plates.

February 19—Dr. Hugh W. MacMillen, Cincinnati. Teeth, Their Comparative Anatomy, Uses, Care and Diseases. (Illustrated.)

February 26—Dr. Robert C. Heflebower, Cincinnati, Ohio. Comparative Study of the Eyes. (Continued.) (Illustrated.)

March 5—Dr. Wm. Seaman Bainbridge, New York City. To be announced.

March 12—Dr. Joseph A. Stucky, Lexington, Ky. Mountain Ophthalmia. Report to Kentucky State Investigating Commission as to Cause, Frequency and Cure. (Illustrated.)

March 19—Dr. Frank U. Swing, Cincinnati. Artificial Eyes and Lenses, Old and New. (Illustrated.)

March 26—Dr. Eben B. Shewman, Cincinnati. The Kidney, Its Anatomy with Reference to Its Function and Pathology. (Illustrated.)

April 3—Drs. Benjamin M. Ricketts, John H. Wilms and DeEnna D. DeNeen. Experiments and Demonstrations.

OKLAHOMA

New Hospital.—Dr. Henry A. Lile, Aline, is building a three-story fireproof hospital to cost about $10,000.

Laboratories Transferred.—The laboratories of the State Board of Health have been transferred from Norman to Guthrie.

Drug Addicts.—Dr. John W. Duke, Guthrie, state commissioner of health, is collecting data on the number of drug addicts in the state who are affected by the Harrison Act.

Personal.—Dr. William M. Cott, Okmulgee, has succeeded Dr. Virgil Berry, Henryetta, as health officer of Okmulgee County.——Dr. Percy A. Smithe, Enid, who joined the American Red Cross in Vienna shortly after the outbreak of the war, has returned to the United States.——Dr. Edward B. Mitchell, Lawton, has returned after a year in Florida.——Dr. William M. Taylor, Oklahoma City, is slowly recovering from the serious injuries sustained in a collision between his automobile and a passenger train.

PENNSYLVANIA

Personal.—Dr. Clinton T. Saylor, Rockwood, who was operated on recently at the Memorial Hospital, Johnstown, for appendicitis, is reported to be convalescent.

Hospital Cornerstone Laid.—The cornerstone of the hospital of the Masonic Home, Elizabethtown, was laid with impressive ceremonies, September 29. Gifts of $52,000 were announced for the hospital, which is being erected as a memorial by the Freemasons of Philadelphia, and is to consist of five buildings to cost altogether about $175,000.

Cannot Provide for Consumptives.—There are said to be 1,107 sufferers from tuberculosis in Pennsylvania on the waiting list of the three sanatoriums of the state. These sanatoriums at Mont Alto, Cresson and Amburg are overcrowded, and the State Board of Health cannot begin the erection of more buildings because of the cutting down of the appropriation for this purpose.——The 115 tuberculosis dispensaries scattered through the state treat on an average of 10,000 cases a day, and in addition a state nurse makes stated calls at the home of each of these patients.

Sixty Typhoid Cases at Shippensburg.—Sixty cases of typhoid fever and twenty-eight suspects were reported October 7 to the State Health Department from Shippensburg. Six health department engineers and nurses are now on the ground aiding the health authorities of the town. A temporary filter plant has been constructed, and an emergency hospital for the treatment of the more advanced cases established. The source of contagion has now been definitely located in the water supply of the town, which comes from springs on state forest reservation plots. The Cumberland Valley State Normal School has been affected, and four girls, two residing in Carlisle and two in Harrisburg, have been sent to their homes. Other cases are being treated in the school infirmary.

Philadelphia

Endowment for Medical College.—It was announced at the formal opening exercises of Hahnemann Medical College, September 27, that the institution would receive at least $50,000 as an endowment through the will of the late Dr. Edward R. Greggs of Pittsburgh.

Union Meeting of Pediatric Societies.—A joint meeting of the Philadelphia, New York and New England pediatric societies will be held in Philadelphia, November 8 and 9. A series of clinics is being arranged, and through the courtesy of the local committee an invitation is extended to the members of the American Association for the Study and Prevention of Infant Mortality.

Hospitals Plan Whirlwind Campaign.—The Children's Hospital campaign for a fund of $500,000 will be under the direction of E. T. Stotesbury, Arthur H. Lea and other prominent citizens, and will begin on October 18, to last ten days.——The Mercy Hospital and School for Nurses, which sets $150,000 as the goal, will start on October 20. The superintendent of the hospital, Dr. R. B. Jackson, sent a letter to the Children's Hospital Committee pleading with it to select another date, as the Mercy Hospital had been planning its campaign for the last six months.

Child Federation Election.—Dr. Joseph S. Neff, former director of the Health and Charities, was chosen president of the Child Federation, at its annual meeting, October 7. He succeeds Edward W. Bok, who declined reelection, but was chosen honorary president. F. Wallis Armstrong, Dr. Samuel McClintock Hamill and Francis S. McIlhenny were elected vice presidents, and J. Ernest Richards, treasurer. The board of directors will include the officers and the following: Albert P. Gerhard, John D. Johnson, George C. Shane, Dr. Henry D. Jump, Mrs. Thomas Robins, Mrs. Alfred Stengel, Charles Z. Tryon and Ernest L. Tustin.

Personal.—Dr. Raymond T. Wayland has gone to San Jose, Calif., where he has been placed in charge of the construction of a large hospital.——Dr. Ruth Webster Lathrop, professor of physiology in the Women's Medical College of Pennsylvania, Philadelphia, has been nominated by the faculty to fill one of the six vacancies in the board of education.——Dr. William C. Hollopeter, for fifteen years professor of pediatrics in the Medico-Chirurgical College of Philadelphia, has retired from the teaching faculty.——Drs. David N. Vogt, Joseph P. Garvey, Robert W. Rubin and Samuel L. Immerman have passed the examination of the Civil Service Commission for resident physician of the bureau of health.——Dr. William B. Swartley sailed September 18 to join the American Ambulance Hospital at Paris.

National Committee Campaign on Feebleminded.—Headquarters have been opened in the Empire Building by the recently formed Committee on Provision for the Feebleminded, a national organization formed to disseminate knowledge concerning the menace of feeblemindedness, and to initiate methods for its eradication. The work of the committee is being financed by private subscriptions. The board of directors includes: chairman, Dr. Milton J. Greenman, director of Wistar Institute; R. Bayard Cutting, member board of directors of training school at Vineland, New Jersey; Dr. Charles H. Frazier, president of the Pennsylvania Public Charities Association, Philadelphia; Bleecker van Wagenen, member of the board of directors, training school at Vineland, New Jersey; Mrs. C. C. Rumsey, New York City; Henry V. Osborne, judge court of common pleas, Newark, N. J.; Mrs. Caroline B. Wittpenn, Hoboken, N. J.; E. R. Johnstone, superintendent of the training school, Vineland, N. J., and Dr. Thomas W. Salmon, medical director of the National Committee for Mental Hygiene, New York City.

TENNESSEE

Public Health Sunday in Nashville.—Prominent physicians occupied the pulpits in the National Church, October 17, and preached the gospel of sanitation and health preservation.

Health Inspection Tour of Middle Tennessee.—Dr. Reese Q. Lillard, Nashville, secretary of the State Board of Health, accompanied by Dr. Olin West, Nashville, of the Rockefeller Sanitation Committee, and Dr. John A. Ferrell, New York City, assistant inspector-general of the International Health Commission, started on a health inspection tour of middle Tennessee, September 28.

Reporting Tuberculosis.—In a report, September 16, to the city commission, it was shown that the physicians of the city had reported only nine cases of tuberculosis in Chattanooga during the previous four months, while there had been forty-five deaths from the disease. The state law makes it compulsory on the part of physicians to report this disease, and they were severely criticized by Commissioner Huffaker for their failure to do so. The names of tuberculosis patients are kept secret by the department.

Personal.—Dr. Heber W. Jones, Memphis, who has been seriously ill in the Baptist Memorial Hospital, is reported to be out of danger.——Dr. Samuel W. Hodge, Knoxville, has returned after several months' work against typhus fever in Serbia. For his services, Dr. Hodge received the decoration of the cross of the Order of St. Savo from King Peter I.——Dr. J. Victor Henderson, Lafollette, company physician for the Lafollette Coal and Iron Company for the last nine years, has resigned, and after a term of postgraduate study in the East, will practice in Knoxville.

UTAH

Personal.—Dr. David W. Henderson, Brigham, has been appointed local physician for the Ogden-Logan and Idaho Electric Railway Company.

New State Officers.—At the twenty-first annual meeting of the Utah State Medical Association held in Salt Lake City, September 28 and 29, under the presidency of Dr. Robert S. Joyce, Ogden, the following officers were elected: president, Dr. Eugene W. Whitney, Salt Lake City; vice presidents, Drs. Lashbrook B. Laker, Eureka; Charles F. Osgood, Ogden, and Frederick Dunn, Springville; treasurer, Dr. Howard P. Kirtley, Salt Lake City (reelected); councilor, second district, Dr. Thomas C. Gibson, Salt Lake City (reelected); and delegate to the American Medical Association, Dr. Solomon G. Kahn, Salt Lake City (reelected). Salt Lake City was selected as the next place of meeting.

WEST VIRGINIA

Typhoid Epidemic.—Charleston is reported to have the worst epidemic of typhoid fever which has been experienced in many years. The health officer estimates that nearly fifty cases are under treatment. No cause for the epidemic has as yet been found.

Change of Address.—Dr. Samuel L. Jepson, for two years secretary of the State Board of Health, was appointed, under the new law, as state health commissioner, and has removed his office from Wheeling to Charleston, where he occupies rooms in the Capitol Building.

Society Suggests Expansion.—At the August meeting of the Mercer County Medical Society, held at Bluefield, the first steps were taken toward the organization of an association to include Mercer and McDowell counties, W. Va., and Tazewell, Russell and Wise counties, Va.

Hospital Association Formed.—The West Virginia State Hospital Association, composed of physicians and superintendents of state hospitals, was organized at Charleston, September 21, with an initial membership of twenty-five. Dr. George C. Schoolfield, Charleston, was elected president, and Dr. Wade H. St. Clair, Bluefield, secretary-treasurer. The next meeting will be held in Wheeling.

Practice of Medicine and Surgery Defined.—The new law of West Virginia enacted in 1915 says: "The term, 'Practice of Medicine and Surgery' as used by this act shall be construed to be treatment of any human ailment or infirmity by any method. *To open an office for such a purpose or to announce to the public in any way a readiness to treat the sick or afflicted, shall be deemed to engage in the practice of medicine and surgery,* within the meaning of this act."

Hospital Internship Not the Equivalent.—The West Virginia Public Health Council (formerly the State Board of Health) has refused to accept a hospital internship as the equivalent of a year of practice required to those seeking licenses through reciprocity. A year of actual practice is considered necessary to establish a physician's character and ethical conduct. The council is considering the advisability of extending the requirement to two years of actual practice.

WISCONSIN

More Money Needed for Sanatorium.—Bonds were voted by the Milwaukee County board last month for an additional $160,000 which is needed for the Muirdale, the new county tuberculosis sanatorium.

Personal.—Dr. Austin O. Olmstead, Green Bay, who has been critically ill in a local hospital for two months, has recovered and resumed practice.——Dr. Samuel D. Greenwood, Menasha, fractured his arm at the elbow while cranking his automobile, September 30.

Medical Women Meet.—At the annual meeting of the Wisconsin Women's Medical Society held in Milwaukee, October 5, Dr. Mary Piper Houck, La Crosse, was elected president; Dr. Minnie M. C. Hopkins, Oconto, vice president; Dr. Ada B. Chandler, Pardeeville, secretary, and Dr. Ella Chaffee Fay, Whitewater, treasurer. The next meeting will be held in La Crosse, and at this time the medical women of Iowa and Minnesota will be invited to meet with the women physicians of Wisconsin.

CANADA

Hospital News.—The Toronto branch of the Red Cross Society has raised during the past hospital year, ending

September 30, $166,872.——The cornerstone of a new hospital was laid at Port Hope, Ont., October 8. It is to cost $25,000.

More Ontario Doctors for the Front.—Forty doctors from the Toronto military division have been selected by Lieut.-Col. Fredk. W. Marlow for the Royal Army Medical Corps, and they have been ordered to prepare to leave at once. Toronto General Hospital will lose a large part of its house staff as many of the senior house physicians have volunteered and been accepted for overseas service.

Personal.—Dr. Wm. Norman Gilmour, Brockville, Ont., was in Australia when war broke out. He went at once to South Africa and joined the forces under General Botha, afterward proceeding to England, where he joined the R. A. M. C.——Dr. George Musson, Chatham, Ont., has been appointed medical officer of health in that city in succession to the late Dr. William R. Hall. Dr. Musson is at present in France.

Ontario Medical Commission Gets to Work.—Notice has appeared in the public press stating that the commission will hold a public session in the Parliament buildings, Toronto, October 16. The object of this meeting will be to ascertain what bodies or individuals wish to present their views to the commissioner. It is the desire of the commissioner to be in possession of the views of those concerned before entering on any contentious questions.

Bruce Returns to Toronto.—Speaking of Lieut.-Col. Geo. G. Nasmith, sanitary officer with the First Canadian Overseas Force, and formerly chief of the laboratories of Toronto, Lieut.-Col. Herbert A. Bruce, on his return to Toronto, states Dr. Nasmith sent the first report to British headquarters on the gases used when the Germans broke through at Langemarck. Dr. Nasmith's opinion has since proved to be correct, and his recommendations the best means for counteracting their effects. His suggestions were immediately adopted by the War Office. Dr. Bruce made a tour of inspection of Canadian overseas hospitals. Canada has over 5,000 beds in England and about 5,000 beds in France; and there are no hospitals in France superior to the Canadians', is his opinion. He visited No. 2 Canadian Hospital at Treport which is in command of Major J. T. Clark, a former practitioner in Toronto. Major Clark has worked out a particularly good method of admitting patients which enables them to be handled with great rapidity, and his method has been adopted by a number of British hospitals. Dr. Bruce also visited McGill Base Hospital at Camiers.

GENERAL

Meeting of Pellagra Association.—The National Association for the Study of Pellagra will hold its third triennial meeting at Columbia, S. C., Oct. 21 and 22, 1915. An excellent program, covering a complete survey of the pellagra situation, has been arranged.

New York and New England Surgeons to Meet.—The twenty-fifth annual meeting of the New York and New England Association of Railway Surgeons will be held at the Hotel Astor, New York City, October 21 and 22, under the presidency of Dr. William H. Marcy, Buffalo.

Red Cross in Mexico Recalled.—Telegraphic instructions have been sent from Washington to close the Red Cross station in Mexico City and directing Charles J. O'Connor, the Red Cross representative in the Mexican capitol, to return to the United States. The Carranza authorities declare that relief work is no longer necessary in the city of Mexico.

Annual Meeting of American Roentgenray Society.—At the annual meeting of the American Roentgenray Society, held at Atlantic City, September 22 to 25, the following officers were elected: president, A. W. Crane, Kalamazoo, Mich.; vice presidents, W. B. Bowman, Los Angeles, and A. P. Gibbs, Columbia, S. C.; secretary, W. F. Manges, Philadelphia; treasurer, W. A. Evans, Detroit.

Erie Surgeons Hold Meeting.—The annual meeting of the Association of Erie Railway Surgeons was held in Buffalo, September 30 and October 1, under the presidency of Dr. John D. Zwetsch, Gowanda, N. Y. Dr. Salem Heilman, Sharon, Pa., was elected president; Dr. Rufus S. Harnden, Waverly, N. Y., vice president, and Dr. Bertis R. Wakeman, Hornell, N. Y., secretary-treasurer (reelected).

Antituberculosis Conference.—At the third annual meeting of the Mississippi Valley Tuberculosis Conference held in Indianapolis, September 29 to October 1, it was decided to drop Montana, Wyoming, Colorado and Idaho from the conference territory. There were 640 delegates who registered during the session. It was decided to hold the 1916 conference in Louisville, Ky., and the following officers were elected: president, Mr. Walter D. Thurber, Indianapolis; secretary-treasurer, Dr. Dunning S. Wilson, Louisville, Ky.; and councilors, Mr. Courtenay Dunwiddie, Cincinnati; Miss Carol F. Walton, Ann Arbor, Mich., A. W. Jones, Jr., St. Louis; Dr. Walter J. Marcley, Minneapolis, and Dr. Ethan A. Gray, Chicago.

Meeting on Prevention of Blindness.—The first annual meeting of the National Committee for the Prevention of Blindness will be held in the Russell Sage Foundation Building, New York, Nov. 4, 1915. Among the speakers who will be present are Ex-President William H. Taft and Dr. George E. deSchweinitz, Philadelphia. The national committee has a number of exhibits which are loaned to individuals or organizations desiring to promote the work of the prevention of blindness. The committee also distributes a large number of publications. In the year 1914-1915 about 100 blind children, victims of ophthalmia neonatorum, were sent to the various schools for the blind. The number of such children, however, is decreasing as shown by the figures of this society; from 23.9 per cent., for 1910-1911, to 15.1 per cent., in 1914-1915.

Red Cross Christmas Seals.—Over one-half million dollars was raised last year in the United States from the sale of Red Cross Christmas Seals. Much good is derived from the educational influence of the seal campaign as well as by the work which is supported by this huge sum. A banner is presented to the winner making the largest sales among villages, towns, cities, or counties in each of ten groups of localities, classified according to the amount of their population. A similar banner is awarded to the state in each of three groups which sells the most seals per capita. Announcements of the winners in the pennant campaign will be made April 1, 1916. Literature concerning the campaign is furnished by the National Association for the Study and Prevention of Tuberculosis, 105 East Twenty-Second Street, New York, which together with the American Red Cross, conducts this campaign.

FOREIGN

Danish Periodical Index.—A Copenhagen exchange states that the librarians of Denmark have made arrangements to publish an annual index of the contents of the periodicals published in Denmark. There are about 125 on their list.

Deaths in the Profession Abroad.—At Florence Hugo Schiff, professor of general chemistry and brother of the physiologist Moritz Schiff. He was one of the founders of the *Gazetta clinica italiana.*——A. Oppel, professor of anatomy at the University of Halle, aged 53.

WAR NOTES

River Ambulances of the Italian Red Cross.—Six steam barges have been fitted up for this purpose and are doing good service on the Po and Mincio rivers. They take the wounded to the base hospitals at Cremona, Mantua and Piacenza.

Anticholera Vaccination in Italy.—A decree issued, August 22, makes anticholera vaccination compulsory in the army and provides for its application to certain categories or groups of persons in the civilian population as the authorities may deem it necessary. The expense is to be borne by the state.

Notification of Dysentery at Naples.—The prefect of the province of Naples has ordered that all cases of dysentery and those even suspected of dysentery should be reported immediately to the authorities under severe penalty. It is hoped in this way to detect and check epidemics of dysentery and cholera in their incipiency.

The Quirinal Transformed into a Hospital.—The entire first floor of the royal palace at Rome has been transformed into a hospital with 206 beds for the wounded. The famous halls, eleven in number, have been named for the first eleven soldiers decorated for conspicuous gallantry. The queen has planned and equipped this hospital, which is unique in its artistic setting and historied past. Dr. E. Scafi is medical chief of the hospital.

BERLIN LETTER

Berlin, Sept. 15, 1915.

Personal

September 11 Leipzig lost its municipal physician for children, Professor Taube, who died at the age of 63. Through his efforts Leipzig became the first German city to make provision for the children's welfare, especially extending protection to illegitimate children. In 1896 Leipzig instituted the so-called Leipzig system which provided municipal guardianship for these children. Taube further aided in procuring proper care for the nurslings.

The War

BANDAGE MATERIAL

The cessation of the importation of cotton threatened for a time to embarrass seriously the manufacture of bandage material. Both in school and at home the children, and the women as well, began to make lint, and physicians were advocating the use of old bandages which had been disinfected thoroughly. Since then the war ministry has given notice that no fear need be had of a shortage of bandage material and that it was unnecessary for any one to spend time making lint. In fact, the use of lint has been forbidden because the material from which it is made can be made use of to good advantage for other purposes.

RESTRICTION OF SALE OF LIQUOR

The activities of the authorities to regulate the use and distribution of foods have been extended recently to curtailing the sale of whisky and other spirits. The police authorities of Berlin have forbidden such sale between 9 p. m. and 9 a. m. in places in which the service is automatic or where it is rendered by women. No one is allowed to sell any liquor to intoxicated persons. Drug stores may continue to sell brandy for medicinal purposes. The punishment for failure to observe these rules is imprisonment or a monetary fine as high as 10,000 marks ($2,500).

MEASURES AGAINST VERMIN

Continued effort is being made to free the soldiers from vermin and to prevent the spread of epidemics by flies and other insects. Disinfection stations are being built everywhere along the eastern border, usually in the immediate vicinity of railroad depots. Eight such institutions have been constructed in various cities and villages of East Prussia and Poland, and two are now being built in Bavaria near the southern border. Each institution consists of eight individual buildings in which 500 men can be taken care of at one time. After a delay of eight hours these troops are transported further. Each institute can take care of 12,000 men in each twenty-four-hour period. Each of the eight individual buildings comprising such institutions is divided into a clean and an unclean part so that mingling of people is impossible. A chief surgeon is in charge, with two assistant surgeons and three inspectors on his staff. A central powerhouse provides the steam necessary for disinfection and light, power and everything else needed in the institution. Two hundred tons of coal are burned daily in each powerhouse. Laundries, kitchens and administrative quarters are provided. The officers are housed in a building containing bath tubs.

The plan of procedure in each institution is as follows: At the entrance, on the unclean side, every man receives a white net, in which he can place his clothing, and a brown net in which are to be placed other than cloth wearing apparel, such as his helmet, his boots, leggings, knapsack—anything to be sterilized by dry heat. A smaller net is given out in which are placed articles of value such as note books, tobacco, portfolios, etc., and finally a distinguishing mark is placed around the neck of the soldier containing a number which corresponds to that found on each net. Each man does his own packing. The nets containing valuables are gathered together in larger nets. The soldier then enters the institution, having first been given a pair of slippers, deposits the nets containing the leather goods and valuables at one window. At another window he deposits his watch, tobacco, articles of food and anything which does not need to be disinfected. He steps into the waiting room of the unclean side. One hundred and twenty-five men disrobe and each places his clothing in the white net which is taken to the large room in which are the steam disinfecting apparatus. Provision is also made for hair cutting so that soldiers who are in need of tonsorial services may receive them. Each man then takes a shower-bath for fifteen minutes, after which he is given a towel. In ninety minutes the 125 men are cleansed thoroughly, are given new slippers and underwear and pass on to the clean side where they receive their disinfected clothing. In six hours 500 men have passed from the unclean to the clean side, and the disinfection of their leather goods and valuables having now been completed, these articles are returned to them. After eight hours these 500 men have left the institution. During their stay on the clean side the soldiers are also given meals, officers receiving the same food as privates. Each disinfecting station is provided with clean clothes for 100,000 men. All worn-out clothing is replaced. Any article which may be the carrier of vermin or which has been badly worn by usage, and therefore is not worth while disinfecting, is replaced. The soldiers then march into disinfected railway coaches. The employees at each disinfecting institute number 380. Special provision is made for the transportation of horses and trains. The detail in charge consists of one staff officer, six commissioned officers, forty-two noncommissioned officers and 910 men.

Ample provision has been made for water at each place. In Alexandrowo two wells, each 38 meters in depth, were constructed and these furnish sufficient water. At other places river water had to be used, the water having been previously sterilized. The outflow from the institute is also disinfected and conveyed into some running stream. To secure efficient service, good system is absolutely necessary. Everything is provided for and everything is done at a certain time and in a certain way. Bell signals are used to give notice of everything that needs to be done. Everything that is not to be used again is destroyed by fire in a specially provided incinerating oven.

The Russian prisoners are very hard to handle in this regard as they do not cooperate with the German authorities in carrying out these disinfection methods. They bury their vermin infested clothing, or, if possible, sell it to their countrymen in other companies. The reason for such action is not very apparent, although superstition may be at the bottom of it. Therefore, it is unfortunately not possible to carry out these plans for disinfection as effectively among the many thousands of prisoners as one would desire.

It has been determined that the Russians display a much greater resistance to typhus than the Germans. Whereas the mortality among the Russians is only 2 per cent., the mortality among the German doctors and nurses is about — per cent. [This percentage is deleted from the original letter by the censor.] However, strenuous efforts are now being made to rid the Russian prison camps of vermin. Each person is disinfected once a week and it is expected that before long the authorities will have full control of the situation.

It is apparent from what has been said that the entire eastern front has been converted into a huge filter to guard against the spread of epidemics and the carrying of disease. Each man in the army, from the general down to the private, prisoners as well as our own troops, must conform to the regulations made by the military and sanitary authorities before he can enter the German empire.

PARIS LETTER

Paris, Sept. 23, 1915.

The War

QUESTIONS AFFECTING THE WORK OF AN AMBULANCE UNIT AT THE FRONT

At one of the last sessions of the Société de chirurgie de Paris, Dr. R. Picqué, surgeon of the hospitals of Paris, who, since the first day of mobilization, that is, for thirteen months, has been in command of the same ambulance unit, read an interesting paper, showing how ambulances of the old type may be so improved by the aid of the resources of the medical service as to be adapted to the novel and imperative necessities of the present war. The leaving of considerable initiative to the medical heads and the supplying of all their demands have permitted the rapid transformation of obsolete organizations into formations in which all surgical operations can be performed. If circumstances permit the units to remain stationary for a considerable length of time, they can be extended into veritable front-line hospitals without losing their essential mobility.

Picqué was therefore surprised to hear at the meeting of the society, during numerous discussions on military surgery, the practical unanimity with which speakers advocated the rapid removal of the wounded toward hospitals at the rear provided with competent staff and surgical equipment.

He was particularly surprised to hear this doctrine applied to patients with important fractures, whose chances for the preservation of their limbs, and even their lives, would be so much enhanced by immediate surgical treatment in the ambulance. In his opinion the present war, from the outset, has shown the importance of intensive surgery of the first line; and the long defensive warfare has singularly favored the extension of this first-line surgery. Such surgery today is possible, not only for surgeons furnished with one of the modern automobile surgical ambulances, not only for those whose good fortune it is is to be able to install themselves in buildings, such as colleges, barracks or châteaux, easily transformable into first-class hospitals, but even for surgeons who, like Picqué, have at their disposal only an isolated mill. With the resources which the medical service offers without red tape to those who wish to make use of them, it is easy for any man of initiative to create an organization which meets all the necessities of present day surgery. In fact, Picqué has seen almost 10,000 wounded men pass through his transformed ambulance to be operated on by him under very satisfactory conditions, the operations including all the procedures that one may be called on to employ in times of war.

Dr. Delbet, professor of clinical surgery at the Faculté de médecine de Paris, while complimenting Dr. Picqué on his ingenuity and perseverance and the methodical way with which he has created his present organization, thinks there is notwithstanding a defect in the principle. Whatever Picqué may say, the organization has thus lost the essential character of an ambulance unit, namely, mobility. Moreover it is installed too near the firing line, that is, only 8 kilometers away. In warfare in which the troops are incessantly in motion, at 8 kilometers one is exposed to the fluctuations of combat; in the present war one is exposed to ordinary shells. The wounded greatly need rest and quiet; they have neither of these in the midst of the noise of cannonshot and the still more disagreeable noise of bursting shells. The distance at which the ambulance unit should be stationed, moreover, depends on the means of transportation. With horse-drawn vehicles, 8 kilometers is a long distance to traverse. It takes no more time to traverse 18 or 20 kilometers with an automobile. For these reasons the superior consulting commission of the medical service has demanded that surgical ambulance units provided with numerous automobiles for the transportation of the wounded should be placed 18 or 20 kilometers from the firing line.

Dr. Tuffier, agrégé professor in the Faculté de médecine de Paris and surgeon of the hospitals, likewise emphasizes the danger of ambulances placed too near the firing line. The operating rooms that he has seen installed at the Harazée and at the Four de Paris a few months ago have been nonexistent for several weeks, having been destroyed by the enemy's bombardment. Moreover, immobilized ambulance units, in order to act as real hospitals, ought to possess a considerable number of beds, while, if they accumulate many seriously wounded patients, they may be obliged to remove them too rapidly, which is infinitely more dangerous for the patients than if they had in the first place been sent farther on, 15 or 20 kilometers, before anything had been done for them.

IMPROVEMENT OF THE MEDICAL SERVICE

In response to suggestions made by M. Astier, senator from the department of the Ardèche, for the improvement of the medical service, M. Justine Godart, assistant secretary, has explained the plan of reform which he is putting in practice. In order to utilize more effectively the special abilities of physicians, he has ordered the regional directors of the medical services to report each month particulars with regard to the physicians in their respective regions—the name, the age, the specialty, etc. He has, moreover, recently consulted a commission composed of professional surgeons for the purpose of studying the best orthopedic methods of furnishing cripples with necessary apparatus within the shortest possible space of time. Competitive examinations and the utilization of the professional abilities of pharmacists, dentists and nurses have already been the subject of careful study.

WOUNDS OF THE HANDS BY SMALL PROJECTILES AND THE OPERATIONS WHICH THEY REQUIRE

At a recent session of the Académie de médecine Dr. E. Delorme, medical inspector general of the military medical service, called attention to the fact that manipulations and massage are often insufficient to reduce the deformities of the hand and fingers and the gross functional incapacities produced by wounds of the hands from small projectiles. Under such conditions it is often well to make use of restorative surgery. Amputation, which is the ordinary method of treating crooked, ankylosed and troublesome fingers, is acceptable, in Delorme's opinion, only when well-directed restorative orthopedic surgery has shown itself insufficient. The most important operations for the treatment of wounds of the hands consist of excisions of cicatrices, generally combined with disengagement or restoration of the tendons and reduction of stiffness, sometimes excision of articular extremities or calluses. Direct suture of the tendons being often impracticable, Delorme has recourse to various other well-known procedures. The care of the patients after these conservative operations is very important. It consists in progressive mobilization (passive and active) of the fingers, electricity, compression and massage of cicatrices, compression of edemas, etc.

THE FORM OF CRUTCHES

The minister of war has called the attention of the head physicians of all hospitals to the importance of the form of the crutches furnished or lent to men wounded in the legs. The straight crutch with a single cross piece, if badly padded or ill proportioned, frequently causes paralysis by compression of nerves.

A DUTCH FLYING HOSPITAL

The Dutch steamship *Batavier III*, from Amsterdam, has landed at Havre a flying hospital, organized by private subscription and placed under the command of Dr. Bierens of Haan, who has already directed organizations of this kind in the South African war of 1899-1901 and the Balkan wars. The staff comprises, besides Dr. Bierens, 4 physicians, 26 female nurses and 5 male nurses. This Dutch hospital unit, composed of 200 beds and capable of being moved in forty-eight hours, was sent to Paris, where it was received at the Saint Lazare station by representatives of the assistant secretary of the medical service and by Medical Inspector-General Dziewomski, director of the medical service of the military government of Paris.

AN AMERICAN GIFT

Mr. Frederick H. Allen of New York has just remitted to the president of the municipal council of Paris, in the name of the Committee of Mercy, of which Mr. Allen is president, the sum of 21,000 francs ($4,200) for the Oeuvre des trains de blessés.

LONDON LETTER

LONDON, Sept. 24, 1915.

The War

THE DEARTH OF ARMY SURGEONS

The difficulty of obtaining a sufficient number of surgeons for the army still remains a pressing problem. Though nearly a fourth of the whole profession is engaged in military duties in one form or another, there is still a shortage of nearly 2,000. A subject which has been under the consideration of one of the war emergency committees (bodies formed under the auspices of the British Medical Association) is the making of some arrangement in the event of physicians dying while on military service. It is thought that those who join would feel the sense of responsibility to their families less overburdening if some arrangement was in force for looking after their interests in the event of death. It has been agreed to form small local subcommittees, consisting of a few men of high standing in the local profession, to act as professional advisers and to collaborate with the legal executors of those who die. Their duty would be either to sell the practice on the best terms available or to see that the practice is carried on until some period after the war when practices again become salable. The Central Emergency Committee of the British Medical Association has issued an appeal to the public pointing out that physicians at the call of duty are going to assist in saving the lives and relieving the sufferings of their countrymen at the risk not only of death and injury but also of the loss of the means of livelihood on their return. While recognizing the right of every one to consult any physician he chooses, the committee appeals to all citizens not to give up their usual medical attendant on account of temporary absence on military duty. All the physicians who have left their practices have either appointed a locum tenens or arranged with neighboring physicians to carry on the work while away. The committee hopes that patients will inform any physician they may consult that their own physician is absent on military service and that they intend to place themselves again under his care when the need arises on his return. The physicians who remain are willingly attending the patients of those on service on the distinct understanding that they shall not be asked to continue to do so after the war. Addressing a board of guardians (the bodies in the country who are entrusted with the care of the poor) a well-known consultant, Sir James Barr, said that all the medical work of the country could be done by physicians over military age and thus all the younger men released for foreign service. "Get men over military age for either part or whole time service for your work until the war is over," he said, "and you will thus be able to set all your young men free to serve their country as they will never have chance of doing again." If the number of men necessary cannot then be found, he considered that the only course would be to apply to the United States.

THE RESPONSE OF THE COLONIES

The manner in which the British self-governing colonies are voluntarily assisting the mother country in this critical hour is an object lesson to the world. Like ourselves, they are willing to make any sacrifices. The federal government of Australia has determined to augment the Australian General Hospital in France by an additional 1,040 beds, bringing the total number up to 2,000. The equipment will be undertaken in England, but the personnel will be obtained in the commonwealth. To staff the second portion of the hospital, thirty-six physicians, fifteen noncommissioned officers, eighty nurses and 170 orderlies will be required. In addition, physicians will be sought from time to time for reinforcements, and the organization of still another unit is under consideration. But, as in England, the demand for medical officers is greater than the supply.

HOSPITAL SHIP SUPPLIED BY NEW ZEALAND

One of the best hospital ships afloat is being equipped in New Zealand. A large steamer, the *Maheno*, is being utilized. Cabins have been removed and the saloon transformed. There are two special wards for five patients, an officiers' ward, a noncommissioned officers' ward and ten wards for the rank and file. One row of beds is composed of fixed cots, while a second is so constructed that the individual cot can be allowed to swing with the movement of the vessel or fixed by means of a metal plate dropping into a slot. It is proposed to admit the more seriously wounded into a special ward amidships, while the less serious cases will be in the space over the transom. The total number of beds for patients is 388, but if necessary the officers' and nurses' drawing room can be transformed into a ward of sixty additional beds. The patients will be received through iron watertight doors at the ship's side, at the level of the lower deck, and hoisted on stretchers which act as mattresses for the beds. Trolleys will be used to convey the stretchers along the passages, and capacious lifts to transfer them from the lower to the main or upper deck. The laundry is well equipped; there are superheated steam cauldrons, electric apparatus for ironing, drying centrifuges, etc. The most modern plant for sterilizing dressings and instruments has been provided, and there is a special system for the automatic delivery of sterilized instruments and dressings on sterile trays on which they are conveyed to the operation theaters. There are two operating theaters, the smaller for minor surgery. The larger is equipped in the latest fashion; white enamel and bright metal are everywhere in evidence. The Roentgen-ray room and the bacteriologic laboratory have been planned with great care. It is said that no field hospital can offer the wounded soldier greater comfort and security, and that few base hospitals are so well equipped.

FLY PLAGUE AT THE FRONT

It was foreseen that a plague of flies was to be expected both in Flanders and in Gallipoli, owing to the conditions inevitably associated with military operations. In Flanders elaborate precautions were taken and date back to April last —that is, before the commencement of the house-fly season, when a circular memorandum on "The Abolition of Flies in Camps, Billets and Hospitals" was issued by the director-general of medical services of the British forces in the field. He pointed out that within the area occupied by the British forces there were concentrated enormous numbers of men and horses, with the result that great quantities of stable manure and other waste organic matter were produced, and that in places along the line of the front there were many unburied bodies. He anticipated that in consequence flies in unparalleled numbers would appear in the course of the summer and autumn, unless adequate measures were taken to prevent breeding. The memorandum contained full instructions for the prevention of the fly plague, and among other fly poisons enumerated was the solution of sodium arsenite which has been recently employed with success in South Africa. Soon after the issue of this circular, a special entomologic commission for service in the field was appointed; it consisted of three well-known entomologists, Mr. Robert Newstead, F.R.S., professor of medical entomology, Liverpool University; Mr. R. W. Jack, government entomologist, Southern Rhodesia, and Captain E. E. Austen of the British Museum. The commission was instructed to study the question on the spot and to inquire into the efficacy of the measures for the suppression of flies adopted or projected. An extensive series of experiments was made with a view to ascertaining the best method of dealing with fly-breeding places which it might be impossible to destroy by fire. As a result, further recommendations were issued. Since then the commission has been continuously engaged in visiting all parts of the front in turn with a view to giving advice to sanitary officers and others. Visits have been paid to a large number of casualty clearing stations, field ambulances and advanced dressing stations, to the town of Ypres, to the trenches and to farms and other billets within range of the enemy's guns. The flies to be dealt with have been house-flies, bluebottle flies, and greenbottle flies. The places where the insects were found to be breeding, and the best practical means for checking them were indicated. In the trenches themselves house-flies have been less numerous than bluebottle and greenbottle flies, although in certain places in the war zone in France and Belgium house-flies have been more numerous than could be wished. The blow-flies, blue and green, have presented greater difficulties. Dr. Shipley has shown that there are two species of bluebottle or blow-flies, *Calliphora erythrocephala* and *Calliphora vomitoria*. They are outdoor flies which enter houses in search of a suitable place to deposit their eggs, by preference on fresh or decaying meat, but even on wounds. The habits of the greenbottle fly, *Lucilia caesar*, are similar, but it is said to prefer fish. Though no practical means for destroying these flies in the trenches on a wholesale scale have been devised, it has been found possible to drive them away by periodic spraying with a suitable fluid.

The Fear of Premature Burial

The fear of premature burial leads from time to time to strange requests. In the latest case a maiden lady bequeathed $100 to her physician on condition that he should see that her throat was cut from ear to ear before burial.

Marriages

Captain William Stevens Shields, M.C., U. S. Army, to Miss Eileen Goggan, Galveston, Texas, at Dallas, Texas, September 25.

Joseph Edwards Kerney, M.D., Providence, R. I., to Miss Bertha Pendorf of Oneida, N. Y., at Philadelphia, September 25.

Welcome Blaine Tilton, M.D., to Miss Violet Deming, both of Clinton, Okla., at Oklahoma City, Okla., September 28.

Sterling Bunnell, M.D., San Francisco, to Miss Maude Compton of Santa Rosa, at Berkeley, Calif., September 22.

Russell Adams Scott, M.D., Evanston, Ill., to Miss Julia Beauchamp Hinkle of Hawesville, Ky., October 14.

Harry Marshall Armitage, M.D., Chester, Pa., to Miss Emily Van Gordon Pudan, of Yale, Okla., recently.

Burlington Earl Smith, M.D., to Miss Annette Florence Erickson, both of Portland, Ore., September 22.

William Lee Gills, M.D., Roanoke, Va., to Miss Elsie Louise Jones of Cheshire, Conn., September 15.

Selmer Martin Johnston, M.D., Buhl, Minn., to Miss Louise de Hass of St. Paul, September 18.

Ray Ranney Kulp, M.D., Davenport, Iowa, to Miss Marie Miller of Fort Wayne, Ind., October 12.

Albert Allen, M.D., to Miss Agnes Marguerite Cross, both of Los Angeles, September 22.

Samuel Bell, M D., to Jean A. Vernier, M.D., both of Detroit, August 13.

Deaths

John Gaunt Brooks, M.D. Jefferson Medical College, 1868; aged 74; formerly a Fellow of the American Medical Association; a charter member and president of the Kentucky State Medical Association in 1887; Southwestern Kentucky Medical Society and Paducah Medical and Surgical Society; commissioned as traveling physician of the Queen of the Hawaiian Islands for the islands of Maui, Molokai and Lanai; for several years a member of the City Council and of the Board of Education of Paducah and of the health boards of Paducah and McCracken County; for more than twenty-seven years a director of the City National Bank of Paducah; died in a sanatorium in Louisville, September 25, from fatty degeneration of the heart. At a meeting of the McCracken County Medical Association, September 25, it was decided to prepare a resume of Dr. Brooks' achievements as a physician, for publication in the Kentucky State Medical Journal.

Edward Nelson Tobey, M.D. Harvard Medical School, 1901; aged 44; a member of the Massachusetts Medical Society; instructor in tropical diseases in the St. Louis University since 1914; demonstrator and research assistant in the Liverpool, England, School of Tropical Medicine in 1906-1907; assistant in bacteriology in his alma mater from 1907 to 1911; instructor in tropical medicine in the Harvard Summer School of Medicine from 1908 to 1910; instructor in pathology in St. Louis University from 1911 to 1914 and thereafter instructor in tropical diseases; assistant city pathologist and bacteriologist of St. Louis; who had been making an investigation of tropical fever in British Honduras; is believed to have been drowned when the steamer *Marowijne* of the United Fruit Company's line, on which he sailed from Belize, August 13, was lost at sea during the hurricane of August 16.

Samuel Kennedy Spalding, M.D. College of Physicians and Surgeons, Keokuk, Iowa, 1874; Bellevue Hospital Medical College, 1882; aged 68; of Omaha; a member of the staff of St. Joseph's Hospital, Omaha; neurologist to the Omaha General Hospital; Professor of Nervous and Mental Diseases in the John A. Creighton Medical College, Omaha; for several years chief of the Douglas County, Neb., insanity board; from 1896 to 1899 Health Commissioner of Omaha; and for several years treasurer of the Board of Education; a veteran of the Civil War; while attending the national encampment of the Grand Army of the Republic in Washington, D. C., was stricken with cerebral hemorrhage, September 28, and died the next day.

John Thomas Gibbons, M.D. College of Physicians and Surgeons in the City of New York, 1889; aged 50; a member of the Association of Military Surgeons of the United States; Major-Surgeon of the Forty-Seventh New York Volunteer Infantry during the Spanish-American War with service in Porto Rico; a member of the staff of St. Catherine's and Bushwick hospitals, Brooklyn, died at his home in that city, October 2, from heart disease.

Stuart Whedon Smith, M.D. University of Michigan, Ann Arbor, 1877; aged 64; a graduate in pharmacy; for twelve years a practitioner of Port Huron, Mich., and later of Denison, Texas, where he made a specialty of diseases of the eye, ear, nose and throat; consulting oculist to the Missouri, Kansas and Texas railroad; died at his old home in Port Huron, Mich., September 24.

William Alexander Graham, M.D. Louisville, Ky., Medical College, 1892; aged 56; a member of the Medical Association of the State of Alabama; formerly president of the Fayette County Board of Censors, county health officer, and secretary and treasurer of the Fayette County Medical Society; died at his home in Fayette, Ala., July 12, from angina pectoris.

Kenneth Frank Junor, M.D. New York University, New York City, 1886; aged 69; of Brooklyn; formerly a Fellow of the American Medical Association; a member of the Medical Society of the State of New York; for several years a missionary of the Presbyterian Church in China and afterward a clergyman of New York City; died in Toronto, Ont., September 26.

Andrew C. Saylors, M.D. Memphis Hospital Medical College, Memphis, Tenn., 1894; a member of the State Medical Association of Texas, a practitioner and druggist of Bynum, Texas; who was stabbed and seriously wounded in an affray in Bynum, in December, 1914, and afterward shot and killed his adversary; was shot and killed at Hillsboro, Texas, October 2.

Frederick Fillmore Burtis, M.D. Albany, N. Y., Medical College, 1898; aged 38; of New York City; formerly city physician and police physician of Schenectady, N. Y., and coroner's physician and deputy coroner of Schenectady County; surgeon of the Panama Railroad and Steamship Company's steamer, *Advance*; died on board that ship, September 6.

Robert H. Hews, M.D. University of Buffalo, 1874; aged 70; of Rockwell City, Iowa; local surgeon of the Illinois Central and Chicago, Milwaukee and St. Paul systems and a member of the Municipal Board of Health; died September 11, at Long Beach, Calif., where he had gone ten days before on account of ill health.

Warwick Evans, M.D. Georgetown University, Washington, D. C., 1852; aged 87; a Fellow of the American Medical Association; professor of anatomy in his alma mater for several years, beginning in 1856; said to be the oldest practitioner in Washington; died at his home September 30, from heart disease.

Luther Hern Keller, M.D. College of Physicians and Surgeons, Baltimore, 1875; aged 63; of Hagerstown, Md.; a Fellow of the American Medical Association; a specialist on diseases of the ear, nose, and throat; died in the Washington County Hospital, Hagerstown, September 30, from heart disease.

Andrew Victor Jova, M.D. College of Physicians and Surgeons in the City of New York, 1883; aged 56; a Fellow of the American Medical Association; visiting physician to St. Luke's Hospital, Newburgh; died at his home in Newburgh, N. Y., September 20, from tubercular laryngitis.

William G. Webb (license, years of practice, Ohio, 1898); aged 79; of Cameron, Ohio; a Fellow of the American Medical Association; for fifty-five years a practitioner; died in the Ohio Valley General Hospital, Wheeling, W. Va., September 27, a few days after a surgical operation.

Samuel Stewart Marr, M.D. Georgetown University, Washington, D. C., 1876; aged 71; for more than forty years in the employ of the General Land Office, Washington, D. C., as chief of the Railroad Division and later as law clerk; died at his home in Washington, September 26.

Mark Dunklin Sullivan, M.D. College of Physicians and Surgeons in the City of New York, 1906; aged 39; a member of the South Carolina Medical Association, and a practitioner of Pelzer; died in Greenville County, S. C., recently from heart disease.

William L. Parmenter, M.D. Homeopathic Medical College, Cleveland, 1873; aged 81; for forty-two years a practitioner of Buffalo; a member of the Buffalo Academy of Medicine; died in Port Stanley, Ont., September 16, from anemia.

Marquis Lafayette Johnson, M.D. Memphis Hospital Medical College, Memphis, Tenn., 1901; aged 67; a member of the Medical Association of the State of Alabama; of Natural Bridge, Ala.; died at Nauvoo, Ala., June 25, from diabetes.

Prudence Fenneman, M.D. Cleveland Homeopathic Medical College, 1899; aged 51; for thirty years a practitioner of Hamilton, Ohio; died at the home of her sister in Canfield, Ohio, September 22, from carcinoma of the kidney.

Charles Louis Carriere, M.D. Homeopathic Medical College of Missouri, St. Louis, 1871; aged 76; for more than half a century a clergyman, and for forty-three years a practitioner of St. Louis; died at his home, September 17.

Mattie Virginia Seams Lee, M.D. Howard University, Washington, D. C., 1911; aged 41; a colored practitioner of Washington, D. C., and later of Charleston, W. Va.; died in Asheville, N. C., August 8, from pulmonary tuberculosis.

William Sheldon Clark Perkins, M.D. College of Physicians and Surgeons in the City of New York, 1860; aged 78; a member of the Connecticut State Medical Society; died at his home in Norwich, Conn., August 7, from diabetes.

Lester R. Lantz, M.D. American Medical University of Pennsylvania, Eclectic, Philadelphia, 1879; aged 55; of Wyalusing, Pa.; died suddenly from cerebral hemorrhage while making a professional call, September 21.

John A. Currie, M.D. Memphis Hospital Medical College, Memphis, Tenn., 1889; aged 56; of Memphis; a member of the Tennessee State Medical Association; died in the Baptist Memorial Hospital, Memphis, September 27.

Payton Chester Madison, M.D. College of Physicians and Surgeons, Chicago, 1893; aged 52; died, October 1, from heart disease.

Charles Henry Scott, M.D. Eclectic Medical Institute, Cincinnati, 1897; aged 48; of Rupert, Ida.; died in that place, July 17, from the effects of injuries received in a collision between his automobile and a railway train.

Claude Earl Bucher, M.D. Northwestern University Medical School, Chicago, 1912; aged 32; of Williamsville, Ill.; was killed October 5 by the overturning of his automobile while responding to a professional call.

Pearl Tinkler, M.D. Barnes Medical College, St. Louis, 1911; aged 26; of Taylorville, Ill.; formerly a Fellow of the American Medical Association; died in the Baptist Hospital, St. Louis, August 9, from septicemia.

Robert P. Sorrells, M.D. Medical College of Georgia, Augusta, 1875; about 60 years of age; a practitioner and druggist of Clarke County, Ga.; died suddenly at his home in Danielsville, Ga., September 24.

M. M. Welsh, M.D. Keokuk, Iowa, Medical College, 1896; aged 52; a member of the Illinois State Medical Society; died at his home in Odell, Ill., September 28, from pneumonia complicating typhoid fever.

Alphonse Joseph Pierre Garneau, M.D. Laval University, Quebec, 1893; aged 48; for more than twenty years a practitioner of Fall River, Mass.; died at his home in that city, September 20, from heart disease.

Herman Delmar Hunt, M.D. Syracuse, N. Y., University, 1874; aged 68; for nineteen years supervisor and for four years postmaster of Preble, N. Y., died at his home in Preble, July 30, from angina pectoris.

David Benjamin Crediford, M.D. Medical School of Maine, Brunswick, 1892; aged 51; a Fellow of the American Medical Association; died at his home in Rialto, Calif., July 18, from angina pectoris.

Orson Pope Kingsley, M.D. Baltimore Medical College, 1907; aged 36; of Brush, Colo.; a veteran of the Spanish-American war, with service in the Philippines; died in a hospital in Denver, September 23.

Willis T. Honsinger, M.D. University of Vermont, Burlington, 1874; formerly a member of the General Assembly from Clinton County, N. Y.; died at his home in West Chazy, N. Y., September 21.

Gideon Hill Morgan, M.D. University of Tennessee, Nashville, 1881; aged 63; died at his home in Fountain City, Tenn., September 29, from tetanus due to a nail wound of the foot ten days before.

Ithamar Davisson, M.D. Baltimore Medical College, 1893; College of Physicians and Surgeons, Baltimore, 1910; aged 60; died at his home in Flemington, W. Va., July 4, from cerebral hemorrhage.

Nicholas Gibbon Moore, M.D. Jefferson Medical College, 1891; aged 48; of Mooresville, N. C.; died at a hospital in Statesville, N. C., September 19, after an operation for disease of the intestine.

James Bates McKinley, M.D. Starling Medical College, Columbus, Ohio, 1891; aged 49; of Harrisburg, Ohio; died at the home of his sister in Columbus, Ohio, September 17, from heart disease.

Elijah A. Shippey, M.D. University of Louisville, Ky., 1854; aged 82; a Confederate veteran; one of the oldest residents of Hot Springs, Ark.; died at his home in that city, September 22.

John S. Mitchell, M.D. University of Pennsylvania, 1852; aged 87; for sixty-five years a practitioner of Bedford County, Va.; died at the home of his daughter near Bedford, Va., September 8.

Marcus Foster Clemmons, M.D. Vanderbilt University, Nashville, Tenn., 1887; of the Baird's Mill neighborhood, near Lebanon, Tenn.; died at his home September 22, from typhoid fever.

John B. Kennedy, M.D. Vanderbilt University, Nashville, Tenn., 1870; aged 70; formerly of Goldsboro, N. C.; a Confederate veteran; died at his home in Grantham, N. C., September 28.

Frank D. Vreeland, M.D. New York Homeopathic Medical College, 1879; aged 64; of Paterson, N. J.; died at the home of his son in Passaic, N. J., October 4, from cerebral hemorrhage.

Hayes B. Jones (license, Iowa, Jan. 10, 1891); aged 69; of Des Moines, Iowa; a veteran of the Civil War; died in the Methodist Hospital, Des Moines, September 18, from pneumonia.

John Hunter Pope, M.D. University of Virginia, Charlottesville, 1868; a Confederate veteran; for many years a practitioner of Marshall, Texas; died in that city about September 20.

Joseph Francis O'Malley, M.D. Rush Medical College, 1892; aged 47; of Ewen, Mich.; died in St. Mary's Hospital, Marquette, Mich., September 19, from carcinoma of the stomach.

Amelia E. Burroughs, M.D. Homeopathic Hospital College, Cleveland, 1881; physician to the Burroughs Place Dispensary, Boston; died at her home in that city, September 25.

Edmund Beckwith, M.D. Homeopathic Hospital College, Cleveland, 1865; aged 78; a pioneer practitioner of Petaluma, Calif.; died in Talmadge, Calif., about September 21.

Charles Isaac Eberle, M.D. University of Michigan, Ann Arbor, 1879; aged 61; of Blairsburg, Ia.; died in Mercy Hospital, Webster City, Ia., September 20, from heart disease.

Thomas Street Norwood, M.D. Tulane University, New Orleans, 1906; aged 34; a Fellow of the American Medical Association; died recently at his home in Norwood, Pa.

Stephen H. Carroll, M.D. New York Homeopathic Medical College, New York City, 1870; aged 73; died at his home in Albany, September 22, from disease of the liver.

George Clarendon Clarke, M.D. New York University, New York City, 1877; aged 65; died at his home in East Douglass, Mass., August 7, from angina pectoris.

Oliver S. Trimmer, M.D. Cleveland University of Medicine and Surgery, 1864; aged 81; died at his home in Pacific Grove, Calif., July 5, from valvular heart disease.

Albert Maldonado, M.D. Bellevue Hospital Medical College, 1887; of San Francisco; died in Lane Hospital in that city, September 15, from atrophy of the liver.

Alfred O. Pitcher, M.D. Homeopathic Medical College of Pennsylvania, Philadelphia, 1867; aged 72; died at his home in Mt. Pleasant, Iowa, September 18.

S. S. Stacy (license, Arkansas, 1903), aged 89; a practitioner since 1868; died at his home in Willcockson, Ark., July 27, from chronic diarrhea.

John Schnee Thompson, M.D. Rush Medical College, 1873; aged 68; died at his home in Palestine, Ill., July 12, from hemorrhage of the stomach.

Charles B. Roberts, M.D. Ensworth Medical College, St. Joseph, Mo., 1890; died at his home in Towanda, Ill., September 21, from heart disease.

Joseph R. Cox, M.D. Cleveland University of Medicine and Surgery, 1896; aged 44; died at his home in New Castle, Pa., August 21, from paresis.

C. J. Hill Chipman, M.D. McGill University, Montreal, 1868; of Port Arthur, Ont.; died in Ottawa, Ont., July 9, from cerebral hemorrhage.

Duncan MacFarlan, M.D. Hahnemann Medical College, Philadelphia, 1875; aged 63; died at his home in Philadelphia, September 26.

Charles C. Taggart, M.D. University of Maryland, Baltimore, 1887; aged 49; died at his home in Marshfield, Ore., September 11.

F. W. Max Klonk, M.D. Baltimore Medical College, 1894; aged 63; died at his home in Oakland, Calif., October 2.

John B. Foster (license, Mississippi, 1880), aged 76; died at his home in Vimville, Miss., September 22.

S. D. Bliss (license, Missouri, 1885), aged 89; of Aurora Springs, Mo.; died in Higginsville, Mo., August 13, from carcinoma of the stomach.

Ephraim A. Santee, M.D. Jefferson Medical College, 1869; aged 77; died at his home in Wapwallopen, Pa., September 16, from senile debility.

C. E. Cox (license, Indiana, 1898), aged 73; died at his home in Cannelton, Ind., August 13, from chronic parenchymatous nephritis.

William H. McDowell (license, Kansas, 1901), aged 71; died at his home in Iola, Kan., August 1, from cerebral hemorrhage.

Charles D. Ware, M.D. Medical College of Ohio, Cincinnati, 1888; died at his home in Bodie, Calif., September 18.

W. F. A. Edney (license, Arkansas, 1903), aged 65; died at his home in Abbot, Ark., July 7, from cerebral hemorrhage.

Emmet E. Whitaker (license, Arkansas, 1903), aged 44; died at his home in Riddle, Ark., July 21, from hemiplegia.

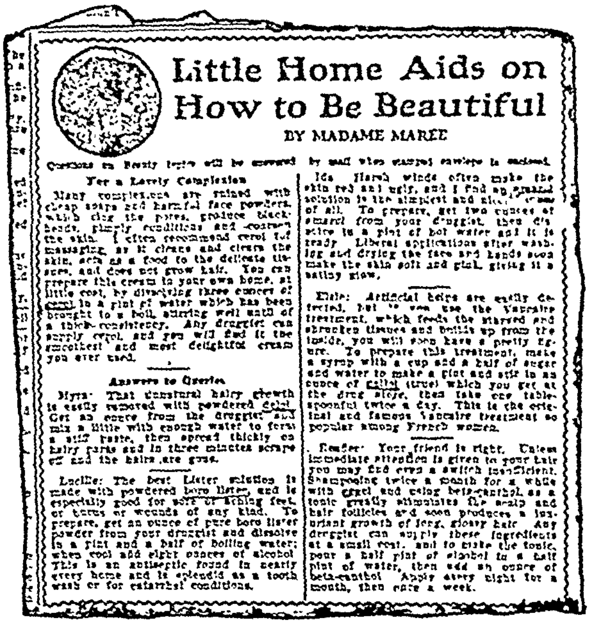
The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

SOME MISCELLANEOUS NOSTRUMS FOR EXTERNAL APPLICATION

AMAROL

Amarol is a so-called "complexion beautifier" advertised under the "prescription fakes" method. It has been exposed by various state health boards. According to the bulletin on "Medical Frauds" issued by the Indiana State Board of Health the stuff is put on the market by the F. W. Scharff Co., Chicago, and has the following composition:



Little Home Aids on How to Be Beautiful

BY MADAME MAREE

Questions on Beauty topics will be answered by mail when stamped envelope is enclosed.

For a Lovely Complexion

Many complexions are ruined with cheap soaps and harmful face powders, which clog the pores, produce blackheads, pimply conditions and coarsen the skin. I often recommend cerol for massaging, as it cleans and clears the skin, acts as a food to the delicate tissues, and does not grow hair. You can prepare this cream in your own home, at little cost, by dissolving three ounces of cerol in a pint of water which has been brought to a boil, stirring well until of a thick consistency. Any druggist can supply cerol, and you will find it the smoothest and most delightful cream you ever used.

Answers to Queries

Myra: That unnatural hairy growth is easily removed with powdered delol. Get an ounce from the druggist and mix a little with enough water to form a stiff paste, then spread thickly on hairy parts and in three minutes scrape off and the hairs are gone.

Lucile: The best lister solution is made with powdered boro lister, and is especially good for sore or aching feet, or burns or wounds of any kind. To prepare, get an ounce of pure boro lister powder from your druggist and dissolve in a pint and a half of boiling water; when cool add eight ounces of alcohol. This is an antiseptic found in nearly every home and is splendid as a tooth wash or for catarrhal conditions.

Ida: Harsh winds often make the skin red and ugly, and I find an amarol solution is the simplest and nicest cream of all. To prepare, get two ounces of amarol from your druggist, then dissolve in a pint of hot water and it is ready. Liberal applications after washing and drying the face and hands soon make the skin soft and pink, giving it a satiny glow.

Elsie: Artificial helps are easily detected, but if you use the Vancaire treatment, which feeds the starved and shrunken tissues and builds up from the inside, you will soon have a pretty figure. To prepare this treatment, make a syrup with a cup and a half of sugar and water to make a pint and stir in an ounce of [illegible] (true) which you get at the drug store, then take one tablespoonful twice a day. This is the original and famous Vancaire treatment so popular among French women.

Reader: Your friend is right. Unless immediate attention is given to your hair you may find even a switch insufficient. Shampooing twice a month for a while with eggol and using beta-canthol as a tonic greatly stimulates the scalp and hair follicles and soon produces a luxuriant growth of long, glossy hair. Any druggist can supply these ingredients at a small cost, and to make the tonic, pour a half pint of alcohol to a half pint of water, then add an ounce of beta-canthol. Apply every night for a month, then once a week.

An advertisement in the form of an Answers to Correspondents department. Each "answer" recommends a "patent medicine" put out by the Scharff-Cooper concern: "Amarol," "Cerol," "Delol," etc.

Epsom salt	95 per cent.
Borax	5 per cent.

The estimated value of the ingredients is 1 cent but it sells for one-half dollar. According to the advertising, Amarol will "make the skin soft and pink, giving it a satiny glow." The F. W. Scharff Co. operates from the same offices as the Cooper Pharmacal Co., "Valeska Suratt," etc.

ANTI-FRECKLE LOTION

This product, according to the Indiana State Board of Health, is put on the market by E. B. Gustin, Logansport, Ind. The Indiana chemists reported that it had essentially the following composition:

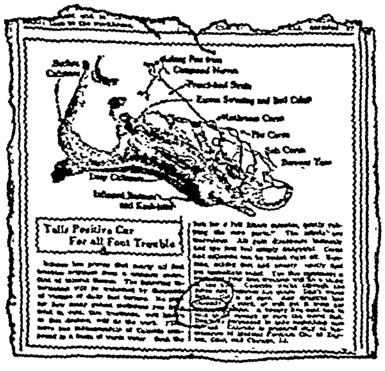
Bichlorid of mercury	1.5 per cent.
Alcohol	2 per cent.
Water	96.5 per cent.

According to the same authority the stuff retails for 50 cents, while the estimated value of the ingredients is 1 cent.

CALOCIDE

Advertisements of Calocide have described it as a "positive cure for all foot trouble." According to one advertisement, when Calocide is used:

> "All pain disappears instantly and the feet feel simply delightful. Corns and callouses can be peeled right off. Bunions, aching feet and sweaty, smelling feet get immediate relief."



Soft Corns
Deep Callouses
Tells Positive Cur
For all Foot Trouble

A typical advertisement of "Calocide."

This marvelous compound, which is also recommended for "frost bites, chilblain, burning, aching tender feet" is put on the market by the Medical Formula Laboratories of Dayton, Ohio, and Chicago. Various chemists have analyzed this preparation and their reports agree in essentials. The following are results reported by the state chemists of Connecticut:

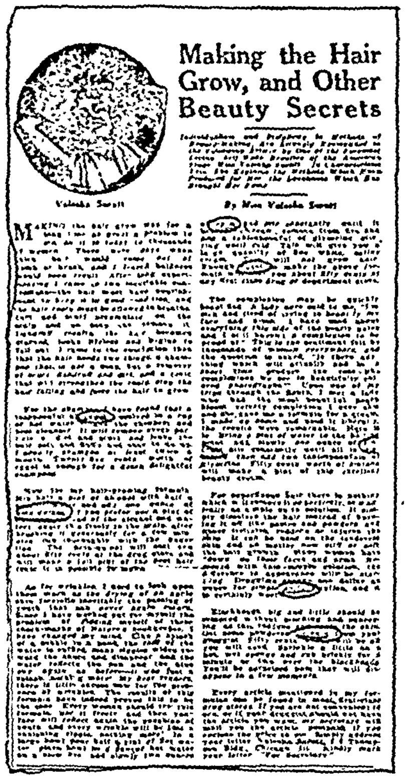
Common salt, about	22.44 per cent.
Borax, about	37.58 per cent.
Alum, about	39.35 per cent.
Tannin	Small amount

Dr. Harvey W. Wiley, who has also analyzed the preparation, states in the book "1001 Tests" that Calocide "might be very drawing and drying to the feet, undesirably so under some conditions."

CEROL

Cerol is another preparation sold on the "prescription fake" method and marketed by the Scharff-Cooper concern, that puts out Amarol, etc. According to an advertisement published in the form of an "Answers to Correspondents" department entitled "Little Home Aids on How to be Beautiful by Madame Maree" Cerol "cleans and clears the skin" and also "acts as a food to the delicate tissues." Various reports from boards of health assign to Cerol the following composition:

Boric acid Stearic acid Perfume



Making the Hair Grow, and Other Beauty Secrets

Valeska Suratt

"Valeska Suratt, Thompson Bldg., Chicago," is a name used by the Cooper Pharmacal Co. in exploiting its nostrums, "Eptol," "Eggol," etc.

CLEAROLA

Clearola is said to be put on the market by G. W. Carpenter, Jaffrey, N. H. It is sold as a preparation which will "whiten the skin" and has been reported on by the state chemists of Indiana, Ohio and Kansas. They all agree in declaring that Clearola is nothing more mysterious than ordinary sulphur.

CUTICLE ACID

This product, put on the market, apparently, by Richard Hudnut of New York is said to "remove dead skin." According to the Kansas State Board of Health Bulletin for August, 1914, Cuticle Acid is mostly water with:

Alcohol	10 per cent.
Oxalic acid	2 per cent.

DERMA-ROYALE

Derma-Royale emanates from the Derma-Royale Co. of Cincinnati. Some years ago it was advertised under such claims as:

> "Cures Eczema and Tetter."
> "Absolutely and permanently removes Blackheads, Freckles, Pimples, Redness, Sun spots and Tan."

The present claims, while not so definite, are no more modest. According to the state chemists of Connecticut, as given in their report for 1914: "This preparation is a dilute alcohol-glycerin solution with small amounts of camphor, myrrh, benzoin and possibly other aromatics in suspension."

EPTOL

"There is little excuse now for the presence of wrinkles. The results of this formula have indeed proved this to be the case. Every woman should try this formula, use it freely and then your face will reflect against the sunshine of youth and every wrinkle will be just a vanishing ripple, nothing more!" Thus, to the gullible, appeals the Cooper Pharmacal Company of Chicago in a fake "Beauty Secrets" department published under the name of "Miss Valeska Suratt." The "formula" referred to is Eptol, plus some glycerin and water. Eptol is a white powder perfumed with rose which sells for 50 cents for a 1½-ounce box. According to the state chemists of Connecticut, Eptol has essentially the following composition:

Borax	37 per cent.
Soap and stearic acid	63 per cent.

FATOFF

Fatoff is supposed to be the "discovery" of one Mary S. Borden and is put on the market by the M. S. Borden Co. of New York City. According to a booklet put out by the concern, "Fatoff has been granted a patent." We find from the patent records that Mary S. Borden of New York City was granted a patent on what she termed a "toilet cream." The patent specifications give the following composition of this product:

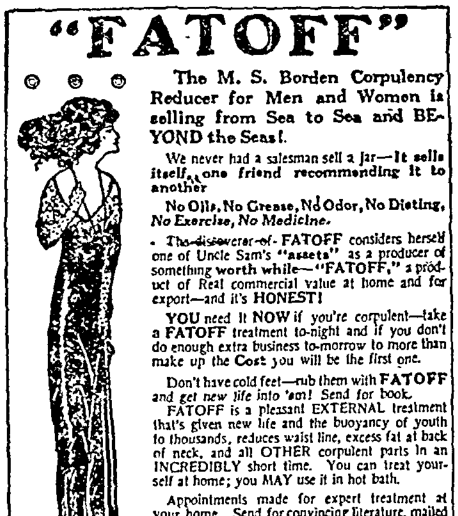
Water	14 lbs.
Washing soap	6 oz.
Extract of bladder-wrack	1 oz.
Washing soda	1 oz.
Potassium carbonate	135 grains
Thyroid gland of sheep	30 oz.
Tincture of iodin	¼ oz.
Perfume	½ oz.

The patent specifications do not give any indication that the preparation is to be used for the reduction of weight; in fact Mary S. Borden states specifically:

> "The object of my invention is to provide or produce a new and useful composition, which, when applied to the skin, will protect the covered part from the air and at the same time operate as a cleanser or purifier for the removal of foreign matters or accumulations."

Elsewhere in the patent specifications, however, Mrs. Borden speaks of the use of her toilet cream "to secure *other* and *further* useful results." [Italics ours.—Ed.] Naturally, there would be no object in using bladder-wrack, thyroid, tincture of iodin, etc., in an ordinary toilet cream sold for cleansing and protective purposes only. All of these drugs, however, are more or less common ingredients in so-called "obesity cures." Some time ago the government published a report in which the federal chemists had the following to say about M. S. Borden's "Fatoff":

> "Analysis shows that the product is a paste made of soap and water containing 10 per cent. soap and 90 per cent. water."



"FATOFF"

The M. S. Borden Corpulency Reducer for Men and Women is selling from Sea to Sea and BEYOND the Seas!

We never had a salesman sell a jar—**It sells itself, one friend recommending it to another**

No Oils, No Grease, No Odor, No Dieting, *No Exercise, No Medicine.*

~~The discoverer of~~ FATOFF considers herself one of Uncle Sam's "assets" as a producer of something worth while—"FATOFF," a product of Real commercial value at home and for export—and it's HONEST!

YOU need it NOW if you're corpulent—take a FATOFF treatment to-night and if you don't do enough extra business to-morrow to more than make up the Cost you will be the first one.

Don't have cold feet—rub them with FATOFF and *get new life* into 'em! Send for book.

FATOFF is a pleasant EXTERNAL treatment that's given new life and the buoyancy of youth to thousands, reduces waist line, excess fat at back of neck, and all OTHER corpulent parts in an INCREDIBLY short time. You can treat yourself at home; you MAY use it in hot bath.

Appointments made for expert treatment at your home. Send for convincing literature, mailed *free in plain sealed wrapper.*

FATOFF FOR DOUBLE CHIN (a chin reducing wonder).

Special Size, **$1.50**

FATOFF (Full Size) **$2.50**

At leading druggists throughout the country or

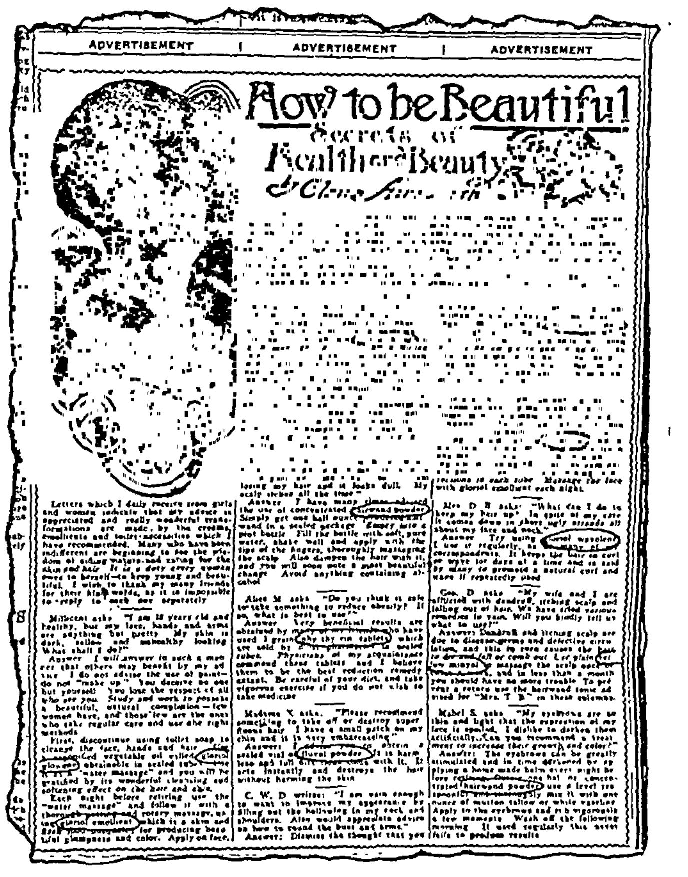
M. S. BORDEN COMPANY

NEW YORK CITY

The Indiana State Board of Health in its bulletin on "Medical Frauds," issued in 1914, states that Fatoff is essentially "soft-soap." It declares further, that while the selling *price of this preparation is $1.50 the value of the ingredients* is 5 cents. From the facts submitted it would seem that, while originally Fatoff may have contained such drugs as thyroid, bladder-wrack, *iodin, etc., it no* longer has these drugs in it. Why should it? It is just as easy to fool the obese with a soft-soap mixture sold under a fancy name at a fancy price as it is to humbug them with a more elaborate product—and the profits are greater!

GLORIOL BALM

This is one of a large group of nostrums put on the market by the Blackburn Products Company, a concern run by two men, one of whom is said to have been in the advertising business and the other in the cigar trade. The Prescription Products Company and the Lesslie Company are two other names under which the same men do business. Gloriol Balm is apparently put out under the name of the Lesslie Company. The advertising is done largely by the "prescription fake" method, usually under the title "The Doctor's Advice by Dr. Lewis Baker" although sometimes by means of an "Answers to Correspondents" department entitled "How to be Beautiful, Secrets of Health and Beauty by Claire Ainsworth." Gloriol Balm is a toilet cream of the "vanishing" type. It is said to "make the skin smooth and clean." It is found listed among medical frauds in the bulletin on this subject issued by the Indiana State Board of Health. According to the Indiana chemists it has the following composition:



ADVERTISEMENT | ADVERTISEMENT | ADVERTISEMENT

How to be Beautiful

Another fake Answers to Correspondents department. The "answers" here recommend "patent medicines" or toilet articles put out by the Blackburn Products Co., of Dayton, Ohio, or of one of its subsidiary concerns.

Stearic acid, soap and borax	23.7 per cent.
Water	76.3 per cent.

GLORIOL GLOWENE

This preparation is put out by the same concern as Gloriol Balm and is advertised by the same methods. According to one advertisement appearing in a fake "Answers to Correspondents" department:

> "Soap is a destroyer of a beautiful skin and I want all my fair readers to discontinue its use. Instead use Gloriol Glowene which is *really* a water massage. . . ."

According to the state chemists of Indiana, of Kansas and of Michigan, "Gloriol Glowene" is soft soap!

ZEMO

Zemo (E. W. Rose Medicine Company, St. Louis, Mo.) is sold as "A Preparation for the Treatment of Eczema, Pimples, Dandruff and Similar Affections of the Skin and Scalp." While, in accordance with the requirements of the Food and Drugs Act, the manufacturer admits the presence of 35 per cent. alcohol in his product he gives no further information regarding its composition. Some of the claims that have been made for this preparation, through the medium of those newspapers that are willing to cater to this sort of business, are:

> "There is nothing known that will stop itching like Zemo."
>
> "You simply apply it on the afflicted part . . . all eczema sores and pains, prickly heat, rash, tetter, inflamed or reddened skin, all disappear."
>
> "It also cures dandruff, which is scalp eczema."
>
> "Every form of Scalp Disease Cured Quick by Zemo."

As is the case with many of the "patent medicines" sold for external application, Zemo is used as a "come-on" for the purchase of another nostrum put out by the same company: "If your case does not readily yield to Zemo use Zemotone, which is primarily a blood tonic and purifier. . . ." Then there are "Zemo Laxative Pepsin Tablets" and "Zemo Soap." The purchaser is told, too, that "if after using Zemo freely the trouble appears worse it indicates that Zemo is *drawing out the germ life.*"

A specimen of Zemo was purchased on the open market and turned over to the Association's laboratory for analysis. An abstract of the chemists' report follows:

> One original bottle of Zemo, manufactured by the E. W. Rose Medicine Co., St. Louis, was submitted to the Chemical Laboratory for examination. The bottle contained a brown fluorescent liquid, acid to litmus. The amount of alcohol was 28.35 per cent. absolute alcohol by volume. Alkaloids, heavy metals and iodids were not found. From the result of the tests made, it would appear that Zemo is a watery-alcoholic solution containing methylsalicylate, thymol, borax, tannic acid, glycerine, menthol and a phenol-like body.

With the veil of secrecy torn aside by the chemists, Zemo stands exposed as a very ordinary mixture sold under misleading and fraudulent claims.

THE PROPRIETARY EVIL FROM A LAY VIEWPOINT

The New York Sun Warns the Public to Shun the Proprietary-Prescribing Physician

In an address delivered before the alumni of the College of Physicians and Surgeons by Prof. Francis Carter Wood, as reported in the *Sun*, the doctor points out that the love of the mysterious is the chief element in the popularity of quack remedies, ranging from the scorched cat's whiskers to the "latest synthetic drugs from Germany." The doctor made facetious reference to the confidence in the new-fangled remedies, without, however, solemnly warning against their use. Derivatives mostly from coal tar and chiefly composed of antipyrin, antifebrin combinations are the most vicious form of empiricism. But the young graduate prescribes them because some young, doubtless well-paid docent has written a certificate to testify to their curative value, because, forsooth, he has tried them on animals, a kind of experimentation to which the student is accustomed to look for enlightenment.

The *Sun* has endeavored to impress on its readers the fallacy, if not the danger, of accepting prescriptions from doctors who, too indolent or unscientific to think out their own prescriptions, write for "Kill or Kurem's" Hydrated Phosphate Compound, or C., D. & X. Company's "Diostenin," or "Professor Chadelle's Cresolated Compound," the composition of which they either do not know at all or accept from the manufacturers. The chief aim of the latter naturally is to popularize these preparations by leaving samples at the doctor's office or offering them in generous quantities for the mere cost of a postal card. This injustice and danger to the lay patient will never be removed, because the medical journals with but a very small exception advertise these preparations, the value and uses of which the manufacturers, with the most brazen effrontery, offer to teach the doctor who will listen.

In looking over the advertising pages of one of the most respectable medical journals, to which our best physicians do not hesitate to contribute, we find in its last issue not less than eighteen proprietary medicines, mostly native, which Dr. Wood did not mention.

As we have repeatedly urged, it rests with the general public to protect itself against lazy or indifferent doctors and their dangerous empiricism by examining their prescriptions and refusing to use any that are written for a medicine that bears the name of the manufacturers or is purchasable in original packages. If in doubt, any one may, by copying the name of the article suspected, ascertain from the druggist before showing the prescription if the medicine prescribed may be bought "by the bottle." Lest this method be regarded as unwarranted, let it be considered that we trust the doctor because we know him and that this trust is misplaced if he prescribes a drug the composition of which he does not know.

Another point suggested by this address is the fact that when Professor Wood said that "the remedy for the love of the mysterious is education," and when he praised the campaign being inaugurated by physicians through bulletins of medical societies and public health officers, "which will abate somewhat the density of popular ignorance," he lost sight of the far more potent influence of those newspapers which devote space to approving comments on these publications and print original articles on the subject, as has been done for many years by the *Sun*, that would never otherwise reach the public.—Editorial, New York *Sun*, Oct. 7, 1915.

Correspondence

American Salvarsan

To the Editor:—It may interest you to know that, in the course of chemotherapeutic researches which Dr. Raiziss, Dr. Kolmer and myself have carried out in the Dermatological Research Department of the Philadelphia Polyclinic during the past year or more, we have reproduced salvarsan and have made a number of new arseno-benzol products. We have given over 100 injections of our salvarsan to hospital patients with excellent therapeutic results and with no untoward effects.

I understand that the supply of salvarsan in this country is exhausted and that the American agents do not know when the drug can be imported from Germany. The American patents are held in the name of Ehrlich and Bertheim, but have doubtless been consigned to the manufacturing company of Lucius and Brüning of Frankfort, Germany.

As salvarsan is necessary to save life as well as to prevent the spread of syphilis, it is eminently desirable that this country should not be deprived of the drug. We could not supply salvarsan to the medical profession at the present time without infringing the existing patent rights of the Frankfort company. To have the patent laws amended would doubtless require congressional action. Should we be permitted to supply the drug to the profession, I think we could offer it at one third of the price which it has recently commanded. All profits accruing therefrom would be devoted to the establishment of a permanent fund for further scientific research.

If you think it desirable to bring this matter to the attention of the Board of Trustees of the American Medical Association, I shall be glad to furnish you with any further information that you might desire.

J. F. SCHAMBERG, M.D., Philadelphia.

[NOTE.—Bearing on the subject-matter of Dr. Schamberg's letter are the following resolutions, which were unanimously adopted by the House of Delegates of the Medical Society of the State of Pennsylvania in session in Philadelphia, Sept. 22, 1915:

> *Whereas*, An important drug, necessary for the cure of disease and likewise the prevention thereof, is no longer available to the medical profession of this country by reason of the European war, and
>
> *Whereas*, This drug has been produced in this country, but cannot be supplied to physicians because its manufacturer is protected by patents, therefore, be it
>
> RESOLVED, By the Medical Society of the State of Pennsylvania that the Secretary of the Interior or the Commissioner of Patents be respectfully urged to call upon the patentees to supply this drug or permit the same to be supplied by others, or to take such other means as his judgment may dictate to relieve the existing condition.

—ED.]

Sixteenth Century Medical Poets

To the Editor:—The following stanzas by Dr. John Halle, written in 1564, were given me by Dr. George Dock of St. Louis in 1905. To the best of my recollection, Dr. Dock found them while browsing about among the old book shops of London, during the preceding summer. The verses contain much good advice applicable to medical practice today.

I have been unable to trace the history of John Halle. His name is not mentioned in the "Biographical Memoirs of the Most Celebrated Physicians and Surgeons" by Pettigrew, published in London about 1840. I have understood that he was the Dr. John Halle who married the eldest daughter of William Shakespeare. She was born in 1583. The verses were written in 1564, nineteen years before her birth, which would throw some doubt, although it would not contradict, this historical statement. As a commentary on gentlemanly conduct and medical ethics of the sixteenth century, I trust the verses will prove interesting to your readers.

WILLARD J. STONE, M.D., Toledo, Ohio.

GOODLYE DOCTRINE AND INSTRUCTION

By John Halle, 1564

When thou arte callde at anye time,
A patient to see;
And doste perceave the cure to grate,
And ponderous for thee:

See that thou laye disdeyne aside,
And pride of thyne owne skyll:
And thinke no shame counsell to take,
But rather wyth good wyll.

Gette one or two of experte men,
To helpe thee in that nede;
And make them partakers wyth thee,
In that worke to procede.

For in so doinge, thine honestye
Thou shalte well kepe and save;
Also thy patiente thereby
Right greate comforte shall have.

By thys meanes thou mayste haplye learne,
Ryghte seldome sene before;
Of thee, or hym, whych fyrste thee taughte,
Though thou have cunnynge store.

And also if oughte goe a wrye,
Or hinder in thy cure,
The one maye mende the others faulte,
While friendship dothe endure.

The wounded or sore man also,
Shall have no cause to grudge
In you suche uniformitye,
Whyle he maye see and judge.

But one thinge note, when two or moe
Together joyned be;
Aboute the paynfull patient,
See that ye doe agree.

See that no discorde doe arise,
Nor be at no debate;
For that shall sore discomforte hym,
That is in sycke estate.

For noughte can more discomforte him,
That lies in griefe and peyne,
Then heare that one of you dothe beare
To other suche disdeine.

Wherefore what so ye have to saye,
In thinges about your arte;
Let it be done among yourselves,
In secrete and a parte.

With one consent uniformlye
Comforte the wounded man;
But unto some good frende of hys
Express all that ye can.

See thou dispraise none other man
His error though thou knowe;
For sure an other for thy plage,
Shall then like curtyse showe.

[COMMENT.—Dr. Stone seems to have somewhat confused Dr. John Halle with Dr. John Hall.

John Hall, who was born in 1575 and died in 1635, married Susanna Shakespeare, June 5, 1607. He is reported to have been a medical man of more than the average knowledge and ability, and was deservedly held in high esteem. Dr. Hall could not have been the author of the poem printed above if it was written in 1564. He was, however, the author of a book of which the following description occurs in the Surgeon-General's Index:

> Select observations on English bodies; or, cures, both empericall and historicall, performed upon very eminent persons in desperate diseases. irst written in Latine by . . . living at Stratford upon Avon in arwick-shire, where he was very famous, as also in the counties adja-[illegible], as appeares by these observations drawn out of severall hundreds of his, as choysest. Now put into English for common benefit by James Cooke.

Dr. John Halle was borne in 1529. His biography is published in J. Aikin's "Biographical Memoirs," London, 1780, p. 181. In a series of articles on Archaeologia Anatomica by E. Barclay-Smith, published in the *Journal of Anatomy and Physiology*, 1900, xxxiv, 275, his work is especially discussed. He is the author of a book thus described in the Surgeon-General's catalogue.

> An historicall espostulation against the beastlye abusers, both of chyrurgerie and physyke, in oure tyme: with a goodlye doctrine and instruction, necessarye to be marked and followed of all true chirurgiens.

It is probable that the poem printed above is a portion of this work. Barclay-Smith states that:

> The "Compendious work of Anatomie, more utile and profitable than any heretofore in the Englyshe tongue publyshed," annexed to Mr. John Halle's "A most excellent and learned woorke of Chirurgerie," is perhaps the earliest anatomical treatise written by an Englishman, and published in England, now existent, but Halle is far from being the earliest English anatomical writer of whom we have record.

So far as can be determined, the first edition of his work has disappeared completely.

Barclay-Smith states that Halle, like many writers of his age, was bitten with an inexpressible desire to sing. He bursts into poetry on the slightest provocation. The following poem is quoted:

But chieflye the Anatomye
Ye oughte to understande:
If ye will cure well anye thinge,
That ye doe take in hande.

For by the same above the reft,
Ye shall greate fame deserve,
The life of many from manye streightes,
To save and well preserve.

Without the knowledge of whyche arte,
Thou canste not chose but erre:
In all that thou shalte goe aboute
Thy knowledge to preferre:

As if ye cutte or cauterize,
Or use Phlebotomye:
Ye can not but erre in the same,
Without Anatomye.

He is no true Chirurgien
That cannot shewe by arte,
The nature of eurye member,
Eche from other aparte.

For in that noble handye worke,
There dothe nothinge excell,
The knowledge of Anatomye,
If it be learned well.

Endeoure therefore by all meanes,
The same to knowe and cunne,
For when thou haste it perfectlye,
Thine arte is halflye wunne.

For thereby shalt thou understande,
Of eche member in dede,
Their nature and their offices,
And howe they doe procede.

And unto what good use they serve,
As well the leaste as moste,
And by their hurte Prognosticate,
What action will be loste.

Whereby of knowledge and greate skill,
Thou shalt obteine the brute,
And men to thee in generall,
For helpe shall make their sute.

Wherfore all honour, laude and praise,
To God ascribed be,
The Father, Sonne, and holye Ghoste,
One God and personnes three.

—ED.]

The Fate of Bone Transplants

To the Editor:—We have received a letter from Dr. C. A. McWilliams of New York, complaining that our Conclusion 2 on experimental bone work (THE JOURNAL, September 18) was unfair, in that it implied that because of lack of sufficient contact and immobilization, his wounds *suppurated*.

We hasten to correct this impression, as if this interpretation were put on the conclusion it would be manifestly unfair to Dr. McWilliams.

Exactly what we meant was that there was not sufficient contact and immobilization in his dog experiments, and not sufficient contact in his three clinical cases to secure primary union between the transplant and parent bone.

So far as other criticisms of the article by Dr. McWilliams are concerned, they pertain to the scientific value of the contribution, and will be answered at another time if need be.

We hope that the foregoing explanation will make the conclusion plain. W. L. and C. P. BROWN, El Paso, Texas.

[The foregoing letter was referred to Dr. McWilliams who replied:]

To the Editor:—The original article by Brown and Brown is loosely put together, for most authorities consider "free" grafts to be nonpedicled grafts in contradistinction to pedicled grafts (either temporary or permanent). Brown and Brown evidently use the term "free grafts" to mean *noncontacting grafts*, but without any explanation of this fact, as one has to go through the article to learn what is meant. The authors have explained in the preceding letter their use of the term "primary union" in Conclusion 2. Universal application of the term "primary union" makes these words refer to the absence of infection. Brown and Brown have found a new use for these words.

As for the criticism of the lack of sufficient contact and immobilization in my animal and clinical cases to secure "primary union" between the transplant and the parent bone, if we grant, for the sake of argument, that these were insufficient, then these grafts died because of the lack of periosteum, for they evidently had not sufficient life in themselves to live and they could not get nourishment from the lack of contacting points. If, on the other hand, periosteum had been on these grafts, they would all have lived despite the pretended lack of contact and immobilization for there are almost no reported failures of transplants made *with* periosteum. Grafts *with* periosteum have been proved by many to be living entities in themselves and do not need contact with living bone to maintain their own life, e. g., Gill (*Ann. Surg.*, June, 1915) has proved that neither contact nor immobilization is absolutely necessary for the life of the grafts, if periosteum be on them, for he transplanted the entire metatarsal bone with periosteum from one leg of a dog to the other leg. There was no bony contact and no immobilization in any one of the cases, yet five transplants lived perfectly for eight months after the transplantations despite suppuration in all but one case. These transplants are all perfectly normal in appearance. Barth was the originator of the theory that contact is necessary for the life of grafts, but in 1908 he entirely repudiated his original ideas and came to believe that periosteum was the necessary element in their life. Murphy is the sole defender of the contact idea, now backed up by Brown and Brown, but Murphy has never advanced any proofs to support the theory. Whether Brown and Brown have done so is left to the judgment of the profession. In addition there are numerous human transplantations of metatarsals and phalanges of the foot into the metacarpals and phalanges of the hand, which have succeeded perfectly without any bony contact being made. These cases absolutely invalidate the contact theory.

C. A. McWilliams, M.D., New York.

The Relation of Selective Tissue Affinity to Infection

To the Editor:—Your recent editorial on this subject (The Journal, Sept. 25, 1915, p. 1114) would seem to open up the path for important clinical progress. If a pneumococcus which has an affinity for the lungs is grown on artificial mediums, it loses this specificity and is apt to locate in other tissues. It has really become another strain. This selective affinity may be assumed to be due to the fact that the toxins of the particular organism in question are especially toxic to this tissue, and having lowered its resistance, grow there with greater freedom, or that certain tissues themselves do not resist the invasion of these strains, or both.

It would seem that a vaccine produced on artificial mediums would be from necessity another strain, and even though it be an autogenous vaccine, its characteristics would probably differ somewhat. By the use of vaccines prepared from cultures grown on mediums containing homologous tissue extracts, the specificity of the culture would be maintained and a greater number of antibodies produced. For instance, a pneumococcus vaccine intended for use in pneumonia could be prepared from cultures grown on mediums containing extracts of lung tissue. A vaccine to be used in pyelitis could be prepared from culture mediums containing an extract of kidney tissue. This would raise the resistance of the particular tissue involved and produce a vaccine with the same characteristics as that of the invading organism. This theory would naturally have its limitations, but in certain fields would open a new door in vaccine therapeusis.

E. L. Ward, M.D., Santa Fe, N. M.

Progress.—The drama of progress, whether displayed in the evolution of living things or in man's age-long struggle to comprehend the world of which he is a product, stirs the imagination by a warmer appeal. Without it we should miss something that we fain would keep.—E. B. Wilson, *Science*.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will *not* be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

LENGTH OF GESTATION IN ECTOPIC PREGNANCY

To the Editor:—Recently I assisted in an operation for ectopic pregnancy in which the uterus was empty and showed no signs of rupture. The child was alive, fully developed and weighed 9 pounds. The mother claims she was always regular with menstruation and there was never amenorrhea until this, her first pregnancy. She claims further that she has been pregnant fifteen months up to the time of this operation and had felt life for nine months. Can you inform me how many cases are on record in which a child remained alive in ectopic pregnancy longer than nine months? The operation was performed two months ago; mother and child are still doing well.

L. T. H., Idaho.

Answer.—It is well known that the duration of pregnancy frequently exceeds 280 days. Of course the exact duration is never known because there is always uncertainty as to the date of the beginning of pregnancy. Even when there is a single coitus the time of fertilization may be delayed, possibly several days. Numerous cases of pregnancy lasting about 302 days are on record and a few cases between 330 and 336 days are accepted as reliable. No credible reports of gestation prolonged more than 349 days are extant.

Such a report as is given by our correspondent can make no claim to credibility. The mother's assertion that she was pregnant fifteen months or that she had felt life nine months means nothing to the reader of the report. Every pertinent part of the personal and family history bearing on the reliability of the patient should be given. The exact dates of menstruation, cohabitation, nausea, symptoms of disturbance from extra-uterine pregnancy, etc., as far as possible should be stated; likewise the exact weight and length of the child, as well as the state of the development of the bones, should be recorded.

While there are numerous reports of cases of abdominal pregnancy with the child living at term, there are very few in which the child lived beyond the usual term of gestation. Uterine contractions generally occur, accompanied by contractions in the extra-uterine fruit sac, and the child dies. Parry ("Ectopic Gestation," 1876) reports a case of twins, one intra-uterine the other extra-uterine, in which the patient felt the movements of the extra-uterine child seven weeks after the birth of the uterine child. He also cites a case from Grassi, who claims to have felt the fetal movements in a case of abdominal pregnancy twenty-three months after cessation of the menses. These reports are good illustrations of interesting medical gossip that have no claim to scientific credence.

FORMATION OF ALCOHOL DURING DIGESTION—ITS OXIDATION BY THE LIVER—EXTENT OF ACIDITY IN HYPERCHLORHYDRIA

To the Editor:—1. Is alcohol formed in the process of digestion?

2. Is it broken up in the liver?

3. In marked cases of hyperchlorhydria does the acid as such continue in the intestines?

H. A. M., Philadelphia.

Answer.—1. A trace of ethyl alcohol appears to be present in the ileum and probably also in the large intestine during digestion and absorption. It is commonly held that this alcohol is the product of bacterial fermentation of the carbohydrates of the food rather than due to the action of the digestive ferments of the pancreatic and the intestinal juices. But this point is still unsettled. It is indeed, possible that the trace of alcohol present in the intestine is excreted from the blood. A trace of ethyl alcohol seems to be present in the blood of normal persons, even when no alcohol is ingested, and when the absorption of alcohol from the digestive tract is excluded. This trace of ethyl alcohol in the blood is, therefore, a product of tissue metabolism. It is well known that alcohol, once in the blood, is eliminated through all the secreting and excreting organs, including the intestinal mucosa.

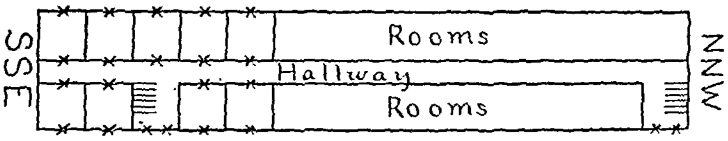
2. There is little or no evidence that the liver oxidizes ethyl alcohol with greater rapidity than do the other organs in the body. It is probable that all the body tissues are capable of oxidizing ethyl alcohol. Experimental work along this line has been concerned with the question whether or not the alcohol is really burnt in the body, and in what way this affects metabolism, rather than with the question as to which particular organ is responsible for the oxidation.

3. In cases of persistent hyperacidity there is hypersecretion. The contents of the duodenum are acid; pylorospasm then occurs, keeping the remaining food in the stomach until sufficient pancreatic juice is secreted to neutralize the acid contents of the duodenum.

VENTILATION

To the Editor:—There is a floor in a school dormitory in this place which approximates this sketch. It is the top floor of a four-story building, and has no overhead ventilation in the hall; therefore all the ventilation is by way of the windows in the rooms and the two staircases. In every instance the window is exactly opposite the door, both being stock size. The rooms are 12 by 12 by 9. There is no method of artificial ventilation in the building, no way of forcing air in or out. The ends of the hall are closed, so that there is no north and south ventilation at all. The building is on a hill to the south of the town, and there are not a dozen residences, and no factories, etc., within a quarter of a mile.

These top floor rooms have been heretofore used for the accommodation of but one pupil, but this year the number of applications exceeds the room-space of the college, and the question of putting two girls to a room on the top floor is being considered. Considered from the standpoint of ventilation, would this be permissible? The average age of the pupils is about 15 or 16.



Sketch of school dormitory; the crosses indicate the location of windows and doors.

Now please don't say that each individual requires 3,000 cubic feet of air an hour and that about 2,500 feet can be passed without perceptible draft through a space of 424 feet, or that in large halls 300 feet per individual is sufficient. I know all that and all the other things about ventilation that do not do me a bit of good. I have to solve a concrete proposition. All girls will not keep their windows open, and in this case it is useless to talk about installing a system of forced ventilation. I know too that on a windy day, if all the windows were opened, you would find it delightful on that floor. The question is, Should I permit them to put two girls in one of those rooms? E. F. Howard, M.D., Vicksburg, Miss.

Answer.—Recent scientific investigation has shown that the bad hygienic effects of an insufficient air supply are dependent on heat stagnation in the body and not on chemical impurity in the air. The easiest and most available method of carrying away the body heat is by means of moving air. Therein lies the chief purpose of ventilation. It is not a question of the quantity of fresh air supplied, but of the quantity of heat that it is capable of carrying away. Hence temperature is also of much importance. If this does not rise above 68 or 69 F., relatively small amounts of air will answer the purpose and no ill effects will be observed. If it goes much above 70, then larger quantities are demanded and some artificial device for maintaining motion becomes necessary.

With these principles in mind we are justified in saying that there should be no objection to placing two girls in a room 12 by 12 by 9 feet and laid out according to the accompanying sketch. The cubic space is quite enough to answer all practical purposes, and the arrangement of doors and windows is such as to make efficient ventilation probable. It is not stated whether the doors are fitted with transoms. It is to be hoped that they are, since such an arrangement will aid materially in the freedom of air movement in and out of the room. As a practical suggestion, it is proposed that the windows of these rooms be supplied with snugly fitting 2-inch boards placed on the sill so that the lower sashes rest on them. This will maintain an open crevice between the upper and lower sashes and secure a ready entrance for air from without. The pupils should be taught that the maintenance of such a crevice may be of value to them.

Recent literature bearing on the principles of ventilation is to be found in the following:

Hill (and others): The Influence of the Atmosphere on Our Health and Comfort in Confined and Crowded Places. Smithsonian Miscellaneous Collections, 1913, Publication 2170.

Lee: Fresh Air, *Pop. Sc. Month.*, April, 1914.

Winslow (and others): Results of the First Year's Work of the New York State Commission on Ventilation, *Am. Jour. Pub. Health*, 1915, v, 85.

Crowder: On the Reinspiration of Expired Air, *Arch. Int. Med.*, October, 1913, p. 420.

TESTS OF PANCREATIC SECRETION

To the Editor:—Please describe the following tests in full:

1. Fulde-Gross stool test of the external secretion of the pancreas.
2. Wohlgemuth's urine test of the external secretion of the pancreas.
3. Volhard's oil gastric test of the external secretion of the pancreas.
4. Loewi pupillary dilatation test.

J. W. Shuman, M.D., Sioux City, Ia.

Answer.—1. The Fulde-Gross trypsin determination method depends on the fact that casein, undigested, is precipitated by acetic acid, while digested casein is not. The estimation is made in units, one unit representing the ability of 1 c.c. stool filtrate to digest 1 c.c. of starch or casein solution.

Fecal solutions of 1:10, 1:100 and 1:1,000 are made and poured into nine test tubes as follows: First three tubes: 1:10 solution, 2, 1 and 0.5 c.c. starch solution 1 per cent., or casein solution 1:1,000. Second three tubes: 1:100 solution, 2, 1 and 0.5 c.c. Third three tubes: 1:1,000 solution, 2, 1 and 0.5 c.c. To each tube are added 5 c.c. of 1 per cent. soluble starch solution or 1:1,000 casein solution. The tube showing digestion, that is, no reaction, by the weakest fecal solution after twenty-four hours' incubation, is taken as the index of digestion. The casein reagent is acetic alcohol (1 per cent. acetic acid may be used); the starch reagent is Lugol's solution.

If a tube containing 1 c.c. of 1:1,000 fecal dilution is the greatest dilution which can digest 5 c.c. starch or casein solution, then 1 c.c. of undiluted fecal filtrate would be able to digest 5,000 c.c. starch or casein solution. This represents 5,000 units. The average normal reading is from 500 to 1,000.

2. Wohlgemuth's method is based on the extraction of a weighed portion of feces with a 1 per cent. sodium chlorid solution and the determination of the amylolytic activity of gradually decreasing volumes of this centrifugated extract, by means of a series of tubes in each of which 5 c.c. of 1 per cent. soluble starch is used as a substrate. After twenty-four hours at 38 C. (100.4 F.) the tubes are treated with a solution of iodin, and the extent of digestion determined colorimetrically. According to Hawk (*Arch. Int. Med.*, October, 1911, p. 553), this method does not yield dependable results when the stools are markedly acid. In his article he gives a modification to overcome this difficulty.

As applied to the urine, this is a test of diastase, 1 c.c. of urine being allowed to act on starch solution. Corbett found that the amount of starch-reducing ferment passed in twenty-four hours is fairly constant, the *d* value or index being 10 to 20 units, each unit representing 1 c.c. of 0.1 per cent. starch solution converted into dextrin in half an hour by 1 c.c. of urine. High readings are found in cases of pancreatic disease, in certain infective conditions and in some forms of eclampsia.

3. Volhard's method is based on the fact that normally there is a slight regurgitation of pancreatic juice into the stomach. The patient receives 1 gm. of magnesium oxid (calcined magnesia), half an hour later 200 c.c. of olive oil or 250 c.c. of sweet cream, and half an hour later again 1 dram of magnesium oxid. The stomach is emptied forty-five minutes later and the Gross method for the examination is carried out. According to Brugsch, the negative findings of trypsin are conclusive only in case erepsin is present.

4. Loewi's test consists of the instillation into the eye of a 1:1,000 epinephrin solution. If dilatation of the pupil takes place within an hour, the test is positive. In cases of pancreatic inefficiency, and occasionally in exophthalmic goiter, the test is positive. Beyond the fact that in these cases there is increased susceptibility of the sympathetic system to stimulation by epinephrin, there is no available explanation of the reaction. It is, of course, necessary to ascertain that the cornea is intact.

SOMNOFORM

To the Editor:—What is the present status of Somnoform as an anesthetic for minor operative procedures and what is its mortality rate in comparison to gas, ether and chloroform? X. Y. Z.

Answer.—Somnoform is the proprietary name of a mixture introduced in 1901. It was originally composed of ethyl chlorid, 60 per cent., methyl chlorid, 35 per cent., and ethyl bromid, 5 per cent. It was found that the mixture soon decomposed, which was largely due to the unstable nature of ethyl bromid.

The formula was changed and the mixture is now said to contain but 1 per cent. ethyl bromid. Small doses increase the pulse rate; large doses reduce it. The heart continues to beat after respiration ceases. Small doses increase the rate and depth of respiration. Large doses cause death by respiratory paralysis through overstimulation of the respiratory center, the diaphragm being in a state of tonic contraction. Breathing is usually easily established by artificial means unless the dose be a very large one, which is probably because the heart is so little affected that anemia of the medullary centers does not occur. Like ethyl chlorid, Somnoform has been employed as a substitute for nitrous oxid before ether anesthesia and for short operations, but has been used mostly by dentists for extractions. It is very rapid in its action, surgical anesthesia, which lasts from one to two minutes, being produced in from twenty to thirty seconds. The dose for adults is from 5 to 7 c.c., and for children 5 c.c. Patients have been kept narcotized for from fifteen minutes to half an hour, but few anesthetists care to risk repeating the dose more than once or twice. About 2 per cent. of the patients vomit and many suffer from intense headache which appears shortly after awaking. It is doubtful if the mixture has any advantage over straight ethyl chlorid, of which it is so largely composed. The methyl chlorid is supposed to hasten anesthesia, while the ethyl bromid prolongs it, but the small percentage of ethyl bromid can hardly be of any value unless a disagreeable odor is an advantage. As with ethyl chlorid, the chief danger with Somnoform is respiratory paralysis. The mortality is 1 in 10,000 or 12,000, which is less than that of chloroform (1 in 5,000 or 6,000), twice as great as that of ether (1 in 20,000 or 25,000) and four times as great as that of nitrous oxid (1 in 50,000). On account of the exceedingly rapid action of both ethyl chlorid and Somnoform it can readily be understood how easily the limits of safety may be overstepped and a dangerously deep degree of narcosis be produced in a few seconds. Reference may be made to Queries and Minor Notes, March 16, 1912, p. 806.

CARAMEL SUGAR FOR DIABETICS

To the Editor:—1. What is the chemistry of fully polymerized sugar as advised in the treatment of diabetes by Grafe (*München. med. Wchnschr.*, June 30, 1914; abstr., The Journal, Aug. 1, 1914, p. 437) and Umber (*Deutsch. med. Wchnschr.*, Feb. 11, 1915; abstr., The Journal, March 27, 1915, p. 1113)?

2. Is this sugar handled by any firm in this country?

Roy Blosser, M.D., Atlanta, Ga.

Answer.—The chemistry of caramel is not well understood. Earlier investigators regarded caramel as a complex substance composed of several ingredients, but later research, especially that of Stolle (*Chem. Centralbl.*, 1899, xi, 1021), shows that the several constituents previously isolated from caramel were not chemical entities. Stolle concluded that caramel prepared by heating sucrose (cane sugar) was a single definite chemical substance having the formula $C_{12}H_{18}O_9$. This, he claimed, is formed by the elimination of water from sucrose as follows: $C_{12}H_{22}O_{11}=C_{12}H_{18}O_9+2H_2O$. The caramel of Stolle is an amorphous substance exhibiting a conchoidal fracture and a red brown color. It melts between 134 and 136 C. and is soluble in water, but insoluble in alcohol. It contains only 0.7 per cent. unconverted sugar.

Commercial caramel, commonly called sugar coloring and used to impart a brown color to various commercial products, is usually made by heating glucose instead of sucrose. It is a dark, syrupy liquid and instead of being a definite chemical body is a complex mixture of several substances, among which are coloring substances, an odorous principle, some undecomposed sugar, a bitter substance probably caramelan, and varying amounts of water.

2. We know of no firm that sells purified caramel in the United States.

The English Side of Medical Education

An article under this title by Mr. Abraham Flexner in the *Atlantic Monthly* for September, makes an important contribution to the literature on medical education. It really furnishes a comparison of the English with the German system of medical education, and shows the defects and the good points in each. Medical education in this country can doubtless benefit much by avoiding the defects, and by adopting the good qualities of the two systems. An abstract of Mr. Flexner's paper follows:

The English medical school is an outgrowth of the English hospital, for it began when the English medical student attached himself to a master whom he followed through the hospital wards. Such additional instruction as the student required—for example, in anatomy and pharmacy—he obtained in schools that grew up outside the hospital, but in close relation to it. In course of time, the separate masters, coming together, formed a "faculty," and their apprentices, being pooled, formed a student body. Thereon the so-called "anatomical schools" became part of the hospital schools. But the medical training was essentially a hospital apprenticeship. The organization consisted of practicing hospital physicians; the resources were merely student fees, and the spirit was intensely and immediately practical. The so-called laboratory subjects, therefore, gradually edged their way into busy hospital schools. Their teaching was at first entrusted to certain members of the hospital staff—usually the younger members—but this soon proved to be unsatisfactory, and the teaching of the underlying sciences was in time differentiated and committed largely to full-time teachers.

The German medical schools vary in extensiveness and completeness, but all possess adequate laboratory and clinical facilities. The preliminary education has been largely along classical rather than modern lines, and without special adaptation to the demands of medical training; yet it has been a serious education of uniformly high quality. Medical teachers have been selected because of scientific eminence. These teachers are called from one university to another as vacancies occur, and in these respects laboratory and clinical teachers are on the same footing. They represent precisely the same university type of activity and ideal. In all these respects English medical education fares badly in comparison.

The English medical school possesses a hospital, and, as a rule, the hospital and its outpatient departments contain material enough for the purposes of instruction, but this material has not been carefully differentiated. Medicine, surgery and obstetrics are recognized as separate divisions; but there is little intensive specialization, and research suffers in consequence. The English hospital also lacks the laboratory equipment and staff needed for the critical study

Miscellany

Effective Industrial Hygiene

An important result of the present "safety first" campaign is the opening of our eyes to a realization of the fact that it is not sufficient to make industries "safe" merely from an accident standpoint: they shall be "safe" also from a health standpoint. This principle is the keynote of an article by J. W. Schereschewsky of the Public Health Service in *Public Health Reports* on a plan for education in the avoidance of occupational diseases and injuries, in which he gives a tentative scheme for accomplishing this object. He says that the approximate average yearly loss through sickness of workers in this country would probably be about the same as it is in Europe—not far from eight to nine days for each of the 25,000,000 to 30,000,000 industrial workers, or an economic loss of $360,000,000 if the average annual earnings are $600. This would not take into consideration the loss due to premature physical decline or reduction in earning capacity, which at present cannot be estimated.

Any plan for improvement in this respect involves the education of every one concerned, which, Schereschewsky says, must be general in nature because of the close interdependence of all the units of society. Improvement in this respect first requires the education of the medical profession and the stimulation of interest in the study of diseases of occupation, the collection of clinical data bearing on occupational diseases, and the promotion of research along these lines. Education of the public is important, because an enlightened public opinion is necessary to the successful carrying out of any measures which may be recommended after careful study of the problems involved.

Schereschewsky says that although industrial workers constitute by far the largest class of medical patients, yet physicians in general regard the study of the relation of disease to occupation as a specialty with which the general practitioner and the specialist in other fields are not closely concerned.

The influence of the industries on health is a subject which has been given little attention in the courses of instruction in medical schools. Hospitals are the chief sources of clinical material and are the natural locations where intensive studies of diseases may be made. In order to utilize this source of information in regard to occupational diseases, the adoption of systematic methods and terms for recording occupations and diseases is necessary. Standard methods of history taking must also be employed. Death certificates should correctly and exactly indicate occupation and use the international system of recording deaths. Accurate information of this kind would be invaluable in the study of the mortality of occupations. Even if this were carried out in a relatively small number of hospitals, it would soon produce an accumulation of valuable information.

The instruction of the public to cooperate in procuring safety in the industries and the securing of personal and collective hygiene and sanitation, Schereschewsky says, must be the result of governmental action, federal, state and municipal, allied with other civic agencies. Minimum standards of industrial sanitation and legislation must be established, and this must be the work of the federal government. The adoption of such standards is the work of the legislatures of the states, but this need not preclude the adoption of additional measures by municipalities or by the employers of labor, labor organizations, etc.

As features of a public educational campaign in the prevention of occupational diseases and injuries, Schereschewsky gives the following outline: permanent exhibits; traveling exhibits including moving pictures; public lectures; bulletins issued for popular distribution by federal, state and local health authorities and by private associations; popular articles in the public press, and instruction in the public schools. All of these measures have been adopted and carried out to a certain extent in a few communities; some have been more generally employed.

Extensive results from any plan of education can be expected only after years of work similar to that outlined above. The employers of labor of course constitute an important factor in the improvement in respect to the prevention of occupational diseases. They too need to be educated, but now the idea is fast gaining ground among them that it is poor social and business economy to subject workers to avoidable industrial hazards. As a consequence, many employers are voluntarily improving working conditions in their plants, supervising the health of their employees and attempting educational measures among them. These measures have been found to yield increased efficiency and economy in production and have fostered the spirit of cooperation.

Liability for Pure Water

In an important decision by the supreme court of New Jersey in the case of *Jones v. Mount Holly Water Company,* the verdict obtained by the plaintiff for $750 damages on account of the illness of his children has been affirmed. It was shown to the satisfaction of the jury and the supreme court that contamination of the water supply by fecal matter, which was declared to be the cause of the illness of the children, was the result of negligence on the part of the water company. The responsibility and duty of a water company to furnish pure water is thus stated by Judge Kalisch:

"It must be borne in mind that the defendant company was in the water-supply business for profit. The plaintiff had paid for the supply which he was to receive, in advance. Hence it became the duty of the defendant company to give to the plaintiff water fit for domestic purposes, including fitness for drinking. Water is a necessity of life, and one who undertakes to trade in it and supply customers stands in no different position to those with whom he deals than does a dealer in foodstuffs. He is bound to use reasonable care that whatever is supplied for food or drink shall be ordinarily and reasonably pure and wholesome. . . . Actual notice or knowledge of the unwholesomeness of the water was not an essential element to be proven in order to establish the defendant's liability. It was sufficient if there was testimony tending to show that the defendant, in the exercise of reasonable care, might have discovered the unwholesomeness and dangerous condition of the water."

Health Test for Garment Workers

The United States Public Health Service has announced the results of an investigation of the garment workers of New York City. About 3,000 garment workers volunteered for physical examination, 1,000 of whom were women. Of this number only about 2 per cent. were free from physical defect or disease. None was found to be suffering from vocational disease but the sedentary industry was found to exercise a deleterious effect on health and efficiency in those having certain defects and diseases. There were recorded in all 13,367 defects of all kinds of which 3,916 were in females, or an average of four defects and diseases in each individual examined. Among the male workers the incidence of tuberculosis was found to be about ten times that in the United States Army and three times the army rate among women. It was of interest to note that the previous military training to which the foreign workers had been subjected before coming to this country had a marked effect in preventing the development of faulty posture habits.

The Antivivisectionists

Mr. Stephen Coleridge is a director and the mouthpiece of the English National Anti-Vivisection Society. Concerning complaint of its attitude toward him and the Society the *Medical Press and Circular* has, among other things, the following to say: "We regard the National Anti-Vivisection Society with the same benevolent amazement with which we regard anything else which is at once picturesque, emotional, and futile—the Society for the Restoration of the Stuarts to the Throne of Great Britain, for example. And, as to Mr.

Coleridge himself, we esteem him to be a great asset to the world of science. He relieves the monotony of accuracy which too frequently besets it. His excursions into it, like the Iron Duke's excursions into the French language, are courageous; they cause distraction and increase the gaiety of nations. A lawyer steeped in sentiment is sufficiently rare to be really remarkable, but when he insists upon floundering about the quagmires of scientific investigation with no better guide than a tremulous tenderness for the nerves of the nether animals, he becomes a priceless public possession. When the Hon. Stephen Coleridge takes the floor to suffer for a rose in aromatic pain, or to writhe vicariously for a narcotized newt, the chorus of sterile spinsters weeps in wistful sympathy, the eunuchs applaud, and the world wonders. For ourselves we emphatically disclaim any semblance of spleen, but we confess to a share in the wonder."

Medicolegal

Another Fraudulent and Unlawful Use of the Mails

(Moses vs. United States (U. S.), 221 Fed. R. 863)

The United States Circuit Court of Appeals, Second Circuit, affirms a judgment against the defendant Moses, who was the general manager of a company that made "oxypathors," and who was convicted of having made unlawful use of the mails. The court says that the indictment charged that the defendant had devised a scheme to defraud; that the scheme was to sell the device called an oxypathor on positive representations that it, among other things, "begets in reality a supplementary breathing through the skin and membranes of the human body"; that its application "increases the amount of oxygen consumed by the body"; that it "has the direct effect of increasing vital combustion and the circulation"; that it "causes the body to attract oxygen from the air"; that "by the proper use of the oxypathor the owner is absolute master of disease in all acute affections and in far advanced stages of the most formidable chronic diseases," etc.; that the scheme was to sell the oxypathor by means of said representations for $35, and to effect the sales by means of letters and advertisements sent through the mail; that the defendant knew these representations to be false; that the oxypathor was in truth and in fact wholly inert, powerless, lifeless, and dead, and utterly worthless and incapable of producing any of the results aforesaid, and was entirely useless for any purpose, except to sell to people who did not know the falsity of said representations; that as one of the instruments of said scheme to defraud, and "in and as a part of the executing of said scheme to defraud, and in attempting so to do, defendant did feloniously, unlawfully, and knowingly cause to be delivered by mail a certain letter," which was set forth. It gave instructions to an agent as to methods of effecting sales, and, as the indictment charged, was delivered through the mail to the addressees. It was contended that the indictment did not charge a crime within any statute of the United States; but the court deems it too plain for argument that the indictment charged an offense under Section 215 of the criminal code. Again, counsel for the defendant treated the cause as if the only alleged false representation was that the oxypathor "would cure all diseases," and that unless the government showed that it was absolutely worthless as a cure for disease the charge in the indictment was not proved. He ignored entirely the other representations. But whether the defendant would have made as large sales if he had merely represented the oxypathor as a cure-all was not important. He went further—quite shrewdly as the court thinks—and sought by his suggestions as to its oxygen-increasing effects to induce its purchase by people who had heard of oxygen and the absolute necessity of its introduction into the system by breathing pure air. If the evidence justified the jury in finding that these assertions were false, and that he believed them to be false, they might find a verdict against him. The physicians called for the government did not undertake merely to express some general condemnation. The witnesses testified that to an experienced physician nothing was indicated by the circumstance that a man felt better after he had lain recumbent for a time with the oxypathor applied to him when the only ailment he testified to was a "lame back" or "nausea." They testified to the value of rest, compresses, hot and cold, of diet, of bathing, of exercise, of sleep, of fresh air, of regularity in the functions of the bowels, of hygiene and sanitation generally. The defendant's literature impressed on all users of the oxypathor the importance of paying great attention to these things, and the government's witnesses testified that the mere circumstance that some one had used an oxypathor at the same time that the treatment was going on was no indication that it contributed anything to the result.

When Damages Allowed for Mental Suffering and Without Evidence Thereof

(Muskogee Electric Traction Co. vs. Rye (Okla.), 148 Pac. R. 100)

The Supreme Court of Oklahoma, in affirming a judgment in favor of plaintiff Rye for damages for personal injuries sustained while he was alighting from one of the defendant company's street cars, says that the rule is well settled that mental pain and suffering, accompanying personal injury or physical pain, is always the subject of compensation. The mental anguish, however, should be connected with the bodily injury, and be fairly and reasonably the natural consequence that flows from it. In this case the evidence tended to show that the plaintiff had suffered a severe injury to his hip and shoulder; that the injury to his shoulder was not only permanent but it was also progressive, that is, it would continue to grow worse as long as the plaintiff lived; that he suffered and was still suffering great physical pain. In such circumstances, direct testimony of mental anguish and suffering, while proper, is not indispensable to a recovery therefor. Damages of this nature are ordinarily determined by the circumstances of the case, as disclosed by the evidence, the amount thereof depending on the seriousness of the injury.

Charges for Medical Attention as Advances to Tenant

(Ligon vs. Roberts (Ala.), 68 So. R. 319)

The Supreme Court of Alabama affirms a judgment, disallowing a charge of $7.50 by the plaintiff for three visits as a physician, in this action to enforce a claimed landlord's lien for advances alleged to have been made to the defendant as the plaintiff's tenant. The court does not say clearly that the plaintiff would under any circumstances have been entitled to such a lien for such services. It says that he testified: "The professional visits that I made to Mr. Roberts' were June 16, 17 and 18. I charged $2.50 for each visit." To whom these visits were made was not shown by the plaintiff. If it be assumed that medical attention to the tenant or his family, or to his laborers, is advances under the statutes, the evidence for the plaintiff did not show that such services were rendered the tenant, the tenant's family, or the tenant's laborers; if rendered pending the tenancy, they might have been performed for some one else at the defendant's residence located on other lands than those rented from the plaintiff.

Use of One Roentgenogram to Illustrate Criticism of Another

(Boddington vs. Kansas City (Kan.), 148 Pac. R. 252)

The Supreme Court of Kansas says that in order to show the nature of the plaintiff's injury, alleged to have been sustained by reason of a defect in one of the defendant's streets, a roentgenogram was used, purporting to show a fractured rib and an injury to the shoulder. In order to elucidate the criticism of this roentgenogram another witness offered a roentgenogram of the breast of a child 5 years old to show the location of the ribs. It was urged that this was incompetent and prejudicial. But its significance was for the jury, who were told it was the picture of a child, and not of a man of the plaintiff's age, and, like an ordinary map, diagram, or model, it might be properly used by way of illustration.

Miscellany

Effective Industrial Hygiene

An important result of the present "safety first" campaign is the opening of our eyes to a realization of the fact that it is not sufficient to make industries "safe" merely from an accident standpoint: they shall be "safe" also from a health standpoint. This principle is the keynote of an article by J. W. Schereschewsky of the Public Health Service in *Public Health Reports* on a plan for education in the avoidance of occupational diseases and injuries, in which he gives a tentative scheme for accomplishing this object. He says that the approximate average yearly loss through sickness of workers in this country would probably be about the same as it is in Europe—not far from eight to nine days for each of the 25,000,000 to 30,000,000 industrial workers, or an economic loss of $360,000,000 if the average annual earnings are $600. This would not take into consideration the loss due to premature physical decline or reduction in earning capacity, which at present cannot be estimated.

Any plan for improvement in this respect involves the education of every one concerned, which, Schereschewsky says, must be general in nature because of the close interdependence of all the units of society. Improvement in this respect first requires the education of the medical profession and the stimulation of interest in the study of diseases of occupation, the collection of clinical data bearing on occupational diseases, and the promotion of research along these lines. Education of the public is important, because an enlightened public opinion is necessary to the successful carrying out of any measures which may be recommended after careful study of the problems involved.

Schereschewsky says that although industrial workers constitute by far the largest class of medical patients, yet physicians in general regard the study of the relation of disease to occupation as a specialty with which the general practitioner and the specialist in other fields are not closely concerned.

The influence of the industries on health is a subject which has been given little attention in the courses of instruction in medical schools. Hospitals are the chief sources of clinical material and are the natural locations where intensive studies of diseases may be made. In order to utilize this source of information in regard to occupational diseases, the adoption of systematic methods and terms for recording occupations and diseases is necessary. Standard methods of history taking must also be employed. Death certificates should correctly and exactly indicate occupation and use the international system of recording deaths. Accurate information of this kind would be invaluable in the study of the mortality of occupations. Even if this were carried out in a relatively small number of hospitals, it would soon produce an accumulation of valuable information.

The instruction of the public to cooperate in procuring safety in the industries and the securing of personal and collective hygiene and sanitation, Schereschewsky says, must be the result of governmental action, federal, state and municipal, allied with other civic agencies. Minimum standards of industrial sanitation and legislation must be established, and this must be the work of the federal government. The adoption of such standards is the work of the legislatures of the states, but this need not preclude the adoption of additional measures by municipalities or by the employers of labor, labor organizations, etc.

As features of a public educational campaign in the prevention of occupational diseases and injuries, Schereschewsky gives the following outline: permanent exhibits; traveling exhibits including moving pictures; public lectures; bulletins issued for popular distribution by federal, state and local health authorities and by private associations; popular articles in the public press, and instruction in the public schools. All of these measures have been adopted and carried out to a certain extent in a few communities; some have been more generally employed.

Extensive results from any plan of education can be expected only after years of work similar to that outlined above. The employers of labor of course constitute an important factor in the improvement in respect to the prevention of occupational diseases. They too need to be educated, but now the idea is fast gaining ground among them that it is poor social and business economy to subject workers to avoidable industrial hazards. As a consequence, many employers are voluntarily improving working conditions in their plants, supervising the health of their employees and attempting educational measures among them. These measures have been found to yield increased efficiency and economy in production and have fostered the spirit of cooperation.

Liability for Pure Water

In an important decision by the supreme court of New Jersey in the case of *Jones* v. *Mount Holly Water Company*, the verdict obtained by the plaintiff for $750 damages on account of the illness of his children has been affirmed. It was shown to the satisfaction of the jury and the supreme court that contamination of the water supply by fecal matter, which was declared to be the cause of the illness of the children, was the result of negligence on the part of the water company. The responsibility and duty of a water company to furnish pure water is thus stated by Judge Kalisch:

> "It must be borne in mind that the defendant company was in the water-supply business for profit. The plaintiff had paid for the supply which he was to receive, in advance. Hence it became the duty of the defendant company to give to the plaintiff water fit for domestic purposes, including fitness for drinking. Water is a necessity of life, and one who undertakes to trade in it and supply customers stands in no different position to those with whom he deals than does a dealer in foodstuffs. He is bound to use reasonable care that whatever is supplied for food or drink shall be ordinarily and reasonably pure and wholesome. . . . Actual notice or knowledge of the unwholesomeness of the water was not an essential element to be proven in order to establish the defendant's liability. It was sufficient if there was testimony tending to show that the defendant, in the exercise of reasonable care, might have discovered the unwholesomeness and dangerous condition of the water."

Health Test for Garment Workers

The United States Public Health Service has announced the results of an investigation of the garment workers of New York City. About 3,000 garment workers volunteered for physical examination, 1,000 of whom were women. Of this number only about 2 per cent. were free from physical defect or disease. None was found to be suffering from vocational disease but the sedentary industry was found to exercise a deleterious effect on health and efficiency in those having certain defects and diseases. There were recorded in all 13,367 defects of all kinds of which 3,916 were in females, or an average of four defects and diseases in each individual examined. Among the male workers the incidence of tuberculosis was found to be about ten times that in the United States Army and three times the army rate among women. It was of interest to note that the previous military training to which the foreign workers had been subjected before coming to this country had a marked effect in preventing the development of faulty posture habits.

The Antivivisectionists

Mr. Stephen Coleridge is a director and the mouthpiece of the English National Anti-Vivisection Society. Concerning complaint of its attitude toward him and the Society the *Medical Press and Circular* has, among other things, the following to say: "We regard the National Anti-Vivisection Society with the same benevolent amazement with which we regard anything else which is at once picturesque, emotional, and futile—the Society for the Restoration of the Stuarts to the Throne of Great Britain, for example. And, as to Mr.

tion that requires most careful consideration, not alone so far as pertains to correction of errors of refraction, but also correction of various anomalies requiring general treatment.

Dr. J. O. Stillson, Indianapolis: I have frequently seen cases in which a very light tinted lens was a great comfort. It is not my habit to allow patients to wear these glasses for any undue length of time, on account of the psychologic effect which might lead their minds astray. However, the only colored glasses with which I have had much experience are the very light bluish ones, which are tinted just enough to take off the glare of light.

Dr. J. D. Heitger, Bedford: To cut out all the ultraviolet light is bad; but if there is an excess, it is advisable that it be toned down. To use a tinted lens as a continual lens is a mistake.

Dr. F. C. Heath, Indianapolis: I am in accord with what has been said as to the necessity of making careful diagnoses so as to ascertain the cause of the sensitiveness to light, and also with regard to avoiding the formation of the smoked glass or tinted glass habit. Some of us are going to an extreme in our opposition to tinted glasses. They certainly have a field of usefulness. A large number of patients coming to the oculist are neurotics—at least there is a neurasthenic element in the case. Whether you call it a psychologic effect or something else, they occasionally get relief from the tinted lens.

Dr. Casey A. Wood, Chicago: Probably the most common ordinary cause of chronic photophobia is some form of heterophoria. The difficulty of using both eyes together with ease and without strain may, of course, be associated, as it often is, with a refractive error; but when you correct the refractive error you really relieve the extrinsic muscle difficulty, and there is where the patient gets relief from the photophobia. Photophobia is almost always due to congestion of the vessels of the choroid. Every case of photophobia that comes to us should be very carefully investigated, and the cause discovered, if possible, and removed.

KENTUCKY STATE MEDICAL ASSOCIATION

Sixty-Fifth Annual Meeting, held at Louisville, Sept. 21-23, 1915

The President, Dr. J. W. Kincaid, Catlettsburg, in the Chair

Pneumonia in Children

Dr. J. Martin, Cynthiana: Outside the general management of each individual case, we must, first, relieve the congestion; second, stimulate the specific phagocytosis, and third, prevent absorption. Symptoms must be relieved as they arise. Drugs intelligently prescribed do good; but when they are ordered carelessly or according to an unreasoning routine, much harm may be done.

Lobar Pneumonia

Dr. Burnett W. Wright, Bowling Green: Developing in the course of some other pulmonary disease, lobar pneumonia may be more or less limited; but when it does not occur as a complication of a previous affection of the lungs, it as a rule affects at least an entire lobe. In the large majority of cases, the condition is acute, but it does occur in a chronic form, resolution occurring with a solidification present for several weeks, after the crisis should have occurred. Occasionally the exudate fails to liquefy, takes on a fibroid change, and the solidification becomes permanent. The question of the immunity to lobar pneumonia is one of individual resistance against the virulence and amount of the infection. The bacterial cause we may consider omnipresent, and repeated attacks must be blamed on damaged lung tissue of subnormal resisting power.

DISCUSSION

Dr. Phillip Barbour, Louisville: The mortality of lobar pneumonia in adults is quite high, while in young children it is not over 5 per cent., and most authorities put it at from 1 to 3 per cent. A child with a deposit of fibrin in the lung, and with a heart strong enough to pump blood through the rest of the lung, will live through a lobar pneumonia. But a child with catarrhal or bronchopneumonia, with every bronchus and bronchiole filled with mucus, will die because it will strangle to death with its own fluid.

Dr. Henry E. Tuley, Louisville: One reason for the difficulty in making a diagnosis of pneumonia is that we are too prone to do away with the stethoscope in the examination of the child's chest. Take an infant of 1 or 2 years of age, and it is absolutely impossible to examine the chest of that child throughout with the ear. It is absolutely essential to use a bell stethoscope which will cover every area of the child's chest. This is particularly true of areas of consolidation, largely of the infra-axillary vein, where it seems that there is considerable distance between the back of the head and the ear. I have seen a case of central pneumonia with delayed transmission of the sounds to the surface that would give bronchial breathing, and except for the clinical signs one would not be able to make a diagnosis for several days until the process had gradually worked its way to the surface. One of the most frequent of the valuable diagnostic signs is the absence of a respiratory murmur over the consolidated area.

Dr. Leon Solomon, Louisville: During the winter of 1893 and the spring of 1894 there visited Kentucky, and in particular Louisville, a type of pneumonia which will be remembered by many of the Louisville physicians, all of the patients dying. I recall the case of a man who died of pneumonia before the diagnosis could be made. Patients in the wards recovered fully from other diseases, were ready to go home, were stricken with pneumonia and were dead within from twenty-four to thirty-six hours, the diagnosis not having been made until necropsy revealed the nature of the disease.

Dr. W. W. Anderson, Newport: I should like to emphasize the point of a sense of resistance under the percussion finger as of use in determining small areas of deep consolidation. In any case of acute inflammation of the lungs or of beginning chronic inflammation, while it is still in the early stages, you will find a resistance just exactly as you find it over the inflamed appendix or gallbladder.

Dr. W. F. Boggess, Louisville: The treatment of pneumonia resolves itself into some very simple, practical way of handling it. First, is plenty of fresh air. The patient should be kept in a room which is well ventilated, with all the windows wide open even in winter time. Some years ago we had a patient in the City Hospital, with double pneumonia, with a temperature of 105, pulse 140, and respiration 60. It looked as though the patient was going to die. He was put under the awning of an open window, and the next morning, instead of being dead, when I raised the awning he was much better. He slept well, and subsequently recovered.

Dr. W. T. Reddick, Paducah: The use of creosote carbonate is very advantageous in the treatment of aged persons and infants who have pneumonia, particularly in those patients who are plethoric and have a full-bounding pulse. Veratrum is especially valuable in these cases.

Dr. Arch Dixon, Henderson: The best treatment for pneumonia is, first, good ventilation, with the windows of the room wide open, and second, cold packs, especially in the sthenic cases; the whole chest should be enveloped with them, and they should be taken off and reapplied. In this way the temperature is reduced and the patients go to sleep. I have used creosote carbonate a great deal and with good results.

A Plea for a More Thorough Examination of Cases Presenting Symptoms Referable to Pulmonary Tuberculosis

Dr. O. O. Miller, Louisville: The following are the indications which should lead us to the examination of the chest for evidence of pulmonary tuberculosis: 1. A family history of tuberculosis in persons complaining of ill health. 2. A history of hemoptysis. 3. A history of pleurisy or fistula in ano. 4. Evidence of past or present tuberculosis of lymphatic glands or other structures. 5. Cough with or without expectoration. 6. Hoarseness or loss of voice. 7. Loss of flesh or strength without obvious cause. 8. Light lividity or restlessness on exertion. 9. Persistent pyrexia, rapid pulse, low blood pressure, or complaint of night-sweating, or repeated chills. 10. Anemia or dyspeptic symptoms in a young adult. 11. A recent acute illness with protracted convalescence, especially from the infective fevers of the young. 12. Continued general weakness following childbirth. 13. History of recent exposure to infection. 14. History of malaise, langor, anorexia or what the patient may call being run down.

Medical Treatment of Incomplete Abortion

Dr. Bernard J. O'Connor, Louisville: Two distinct facts stand out prominently in the causation of hemorrhage and infection. In the former, the uterus contains some foreign body which it is trying to expel, or the musculature of the uterus is impaired, while in the latter, the infectious material has in some manner been introduced from without into the body of the uterus. An unemptied uterus predisposes to infection. The scientific treatment for incomplete and inevitable abortion is to empty the uterus promptly, avoiding at the same time any procedure which might lead to the introduction of infectious material, into either the uterus or the blood stream.

DISCUSSION

Dr. Edward Speidel, Louisville: We should avoid vaginal examination in cases of abortion unless there is a positive indication for them. My treatment of abortion is active interference.

Ossification of the Bones of the Hand

Dr. J. W. Pryor, Lexington: My belief that normal ossification of bones presents evidence of heredity is based on the facts that we may find similar conditions in the chronological order in the ossification of the bones of the carpus, and that when extra epiphyses are found to be present they may be found in the hands of the brothers and sisters. I have encountered only a few instances in which there was an extra epiphysis present, such as that occasionally found at the proximal extremity of the metatarsal bone of the index finger. Unfortunately, when I did find this extra epiphysis present, the phenomenon occurred in most instances in the only children of the parents, and I have not been able to follow the families. I have had abundant opportunity to observe the similarity of the order of the ossification of the bones of the carpus in the hands of brothers and sisters. I have followed these cases through a number of years. In some instances I have made examinations several times during the year, and when necessary during the period of several years in succession in order to obtain results.

Complications of Middle Ear Suppuration

Dr. L. S. Givens, Cynthiana: In the acute diseases of the middle ear cavity which may lead to brain abscesses, the two most vulnerable spots by which infectious matter may enter the brain tissue or its membranes directly are the tegmen tympani or tegmen antri, by erosions or through dehiscences. Labyrinthitis with acute otitis media is usually the avenue to a fatal meningitis in those cases in which death occurs a few days after the beginning of the suppurative process. Secondary involvement of the labyrinth is seldom encountered in chronic suppuration. When present, the mischief has usually been done in the acute stage of the disease, and although both the oval and the round windows may have remained bathed in pus for years, extension to the labyrinth seldom follows. In four of twenty-one cases, the duration of the suppuration was unknown, in seven there was a history of chronic suppuration, while in ten intracranial involvement following an acute suppuration of the middle ear occurred.

DISCUSSION

Dr. William J. Thompson, Newport: Ninety-five per cent. of all middle ear troubles originate in the throat or nose. From the middle ear it is only a step to the antrum, and only a short step from the antrum to the mastoid cells. When the mastoid cells are involved, we may not only have abscess of the brain, but also have the lateral sinuses denuded, and the patient is liable to die before we think he is seriously ill.

Dr. B. A. Bledsoe, Newport: In a chronic otitis media with a large perforation in the drum, with pus escaping from the perforation, only a small part of the necrotic area is seen. The destruction is going on in the entire middle ear and extending back into the mastoid antrum, involving the mastoid cells. Unless tension is increased in the mastoid cells, there are not going to be marked symptoms of mastoiditis. In chronic cases, when the drainage is free, a mastoid inflammation may produce an acute exacerbation, and the most important complication to remember is that of brain abscess.

Dr. W. B. McClure, Lexington: The remedy to prevent this condition is free drainage by opening the tympanum. The general practitioner may very readily, with a good light and the proper instrument, establish drainage, and in a large percentage of these cases the mastoiditis and other extensions following mastoid involvement may thus be prevented. I believe that in every case in which there is a bulging red ear drum, with pain, if an incision is made and the contents of the middle ear let out, not only will the pain be relieved and external drainage established, but complications also will be prevented.

Dr. J. F. Reynolds, Mount Sterling: No doubt many have diagnosed abscesses in the liver, kidney, spleen and various other organs without being able to tell the origin of the septic material. Have these patients ever been asked if they have ever suffered from middle ear suppuration? If we cannot find the origin of the septic material elsewhere, we should always inquire of these patients as to whether or not they have suffered from middle ear inflammation.

Focal Infections

Dr. N. T. Yager, Louisville: In all cases of obscure systemic derangement, a thorough examination of the oral cavity should be made by a competent dentist and roentgenograms taken of every tooth. One should not take the patient's word for the condition of his teeth and mouth. Many teeth are extracted for apical abscesses from which the patient has experienced no local inconvenience. More attention should be paid to physical diagnosis and bacteriology by the dentist and cooperation of the medical and dental professions.

DISCUSSION

Dr. M. L. Ravitch, Louisville: The teeth sometimes play an important part in infections. I recall a case in which the jaw was affected, and the disease was diagnosed as cancer. At my suggestion certain teeth were extracted, and after the use of mild antiseptics, healing took place and very little scar was left. It was not a case of cancer at all but a condition brought about by diseased teeth.

Dr. John J. Moren, Louisville: At one time I began to suffer with pain in my joints and hands, so that shaking hands was absolutely painful to me. I had a lower molar tooth which was hurting me a great deal. I went to a dentist for the purpose of having it extracted, if necessary, but he refused to extract it because he wanted to save it. I decided to take the initiative myself. I had a roentgenogram made, and it showed an abscess in two roots. The tooth was removed, and within two weeks I had practically no pain either in my joints or in my hands. I did not take any medicine.

Dr. Michael Casper, Louisville: It is a common occurrence for patients to have unerupted teeth. A great many cases of facial neuralgia and of headache, especially lateral headache, can be explained on the ground of unerupted teeth which are not discovered until roentgenography is resorted to.

Dr. C. E. Purcell, Paducah: A few years ago a young woman came under my care who had intolerable pain over the side of her face. Her condition had been diagnosed as tic douloureux, and she was advised by a surgeon to have the ganglion resected. He was about to remove the ganglion, but for some reason or other his time was so occupied that he did not get to do it, and the girl was dismissed from the hospital. She went home, her dentist extracted a molar tooth which was badly decayed, and she recovered.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA

(Continued from page 1304)

Treatment of Fractures

DR. JOHN B. ROBERTS, Philadelphia: The essentials of subcutaneous fracture treatment, so far as the injury is concerned, are anesthesia, with comparison of the normal limb and accurate reconstruction of bony contours; verification of line of fracture and accuracy of reduction by Roentgen ray when practicable; anatomic and physiologic knowledge of muscles and bones; well-fitting retentive appliances; early frictions, skilful early mobilization, and careful massage with frequent inspection.

DR. JOHN B. LOWMAN, Johnstown: Open treatment of fractures has taught us that in some cases delayed union is caused by too close approximation, thus inhibiting callus formation, producing bone absorption and leading to infection and necrosis of bone; it has also taught us never to plate a compound fracture. The open treatment is indicated in fractures which cannot be reduced properly, especially complicated fractures around joints. Bone grafting seems to be superior to all other methods, although these other methods have their advantages. In all fractures of the bone shaft, plating is the best method and should be done as early as possible. Out of twenty-five fractures of the shaft of the femur plated, twenty-three patients are back at work at their former occupation; this has been the exception in those treated by the closed method.

DISCUSSION

DR. WILLIAM L. ESTES, South Bethlehem: The American Surgical Association appointed a committee two years ago to standardize as far as practicable the various results as regards treatment of fractures, but at the very outset our work was almost entirely nullified by the fact that we could get proper records from only a very few sources in the United States. For that reason the committee elaborated a form of record which we are trying to have introduced, and which we believe will give us an opportunity to collect data which will finally lead to some sort of result in establishing what ought to be the proper treatment of the ordinary fracture.

DR. P. G. SKILLERN, JR., Philadelphia: Nitrous oxid gas should always be administered to afford the surgeon as well as the patient the best conditions for a complete reduction. After the attempt at reduction, a roentgenogram should be taken. If the fragments are still unreduced, the cycle of administering gas, reducing and making roentgenograms should be repeated. It may be necessary to repeat this cycle two, four or even six times in obstinate cases, but each cycle is harmless, though perhaps slightly inconveniencing to the patient. It is only after such repeated attempts by their failure prove the fracture to be irreducible clinically that operative treatment is indicated. After reduction, a copiously padded and carefully applied fixation dressing should be put on, treating each fracture in an individual and not a routine manner. Of the methods of operative fixation, that by the use of metal plates is the least desirable, and, if indicated at all, metal fixation is best employed for fresh fractures, and not for cases of nonunion. For nonunion, by far the best method is the employment of the autogenous bone graft.

DR. EDWARD MARTIN, Philadelphia: I am in accord with the dictum that metal plates always delay union, and are to be avoided save in exceptional cases. The statistics studied by Estes show that operative treatment is less frequently required in children than in adults. This is in part due to the fact that in the young a moderate deformity has a tendency on use to gradual correction. Such tendency is never exhibited in the adult. In the latter, a good union with moderate and allowable deformity, if the bone be a weight-bearing one, may become on use a crippling and deforming one. Hence, given even a slight angulation of the leg, bone weight bearing should not be allowed for many months.

DR. CHARLES E. THOMSON, Scranton: In regard to the statement that fractures should be treated by skilled surgeons, that is not practicable. Our fractures occur in the country, and the skilled surgeons live in the big medical centers. The general practitioner has to treat many of our fractures. Dr. Roberts says, "Teach your students to treat fractures." This is the key to the situation.

Acute Pancreatitis

DR. JOHN B. DEAVER, Philadelphia: By acute pancreatitis we ordinarily understand the classical severe type, described by Fitz, in which there is hemorrhage and extravasation of pancreatic juice, resulting in profound general shock, intoxication and local destruction of tissues with ensuing gangrene or suppuration. In the last few years, surgery has revealed that the lesser inflammatory lesions of the pancreas are common. It has not been sufficiently pointed out that acute pancreatitis without the severer manifestations of hemorrhage and extravasated ferments is not uncommon. Many cases in which operations have been performed have been unrecognized, and attributed to disease of the biliary tract. The treatment of pancreatitis has not as yet been standardized because of lack of knowledge of its exact cause and the mechanism of its production. Pancreatitis is a result of infection or duct obstruction or a combination of the two. Operative intervention should aim to establish the cause and relieve it. Infective pancreatitis secondary to disease of the biliary tract should be treated by the measures adapted for the relief of biliary infection. Obstructive pancreatitis due to stone in the papilla of Vater or to other abnormality of the papilla demands relief of the obstruction. In ultra-acute cases, the question of operability enters strongly and may forbid everything except simple drainage. I protest against the sending of acute abdominal cases to the medical wards of the hospital. By the time they reach the surgeon, valuable time has been lost.

DISCUSSION

DR. ERNEST LAPLACE, Philadelphia: There has always been some mystery connected with the question of disease of the pancreas. This question of pancreatitis is in the same condition as appendicitis was fifteen or twenty years ago. There is no such condition as an uncomplicated pancreatitis any more than there is an uncomplicated appendicitis. When a violent pain is felt in the epigastrium with symptoms of shock, that patient should be transferred to the surgeon immediately and we will drain at once. Some of these cases are accompanied by a dilated duodenum with intestinal sepsis as a predisposing cause to the infections which will travel up through the ampulla of Vater and carry to the pancreas whatever infection has found its way up there. The complications of pancreatitis and cholecystitis travel together. It is the same infection. Dr. Deaver first called attention to the lymphatics. The duodenum and pancreas are supplied by the same lymphatics and the spleen and body of the pancreas by the same lymphatics. I make a plea for early operation.

DR. LAWRENCE LITCHFIELD, Pittsburgh: I have been associated with medical wards for the past twenty-five years, and I have often regretted the time lost by the fact that these cases were first sent to the medical wards. I wish to emphasize also the fact that valuable time is lost in many cases by delaying operation too long in the hope of making a definite positive diagnosis. There are several conditions in which an operation must be undertaken before a positive diagnosis can be made, if the patient's life is to be saved.

Management of Toxic Goiter

DR. CHARLES H. FRAZIER, Philadelphia: Toxic goiter may begin as simple goiter and be transformed into the toxic variety or the true exophthalmic goiter. The principal distinction to be made surgically is in reference to the severity of the case. The treatment of this condition belongs essentially to the domain of surgery. If the circumstances of a person suffering with moderate thyrotoxicosis are such as to render impracticable a prolonged period of rest, I strongly urge immediate operation and the removal of as much of the offending gland as conditions indicate. The mortality is insignificant. I have not lost a case of this type. In a grave form of intoxication the watchword is caution. It is out of the question to say what the order of procedure should be until after the patient has been under observation in bed for a few days, during which a study of the body functions and all the available secretions and fluids has been made. Each case presents its own problem as to whether it should be treated by boiling water injections, ligation of one or more vessels at one or more sittings or by partial thyroidectomy. A good working rule when in doubt is to err on the side of conservatism. A patient should not be operated on in the stage of acute exacerbation. Rest is the most fruitful nonoperative measure. I have tried the Roentgen rays and radium without appreciable effect. The relation of the thyroid to other ductless glands, especially the thymus, should not be overlooked. In seventy-six thyroidectomies for toxic goiter I have had no deaths, and in twenty-four ligations two deaths. I would not at this time consider such cases as the two fatal ones suitable for that particular operation at that cycle of the disease.

DISCUSSION

Dr. John D. Singley, Pittsburgh: Careful interpretation of the history and of the clinical manifestations of toxic goiter has taught us to avoid operation during the periods of exacerbation and in the final stages of the disease. To this, much more than to any great improvement in operative technic, is due the marked reduction in operative mortality which has taken place in recent years. The earlier that goiter patients are operated on, after the onset of toxic symptoms, provided operation is not done during acute exacerbations, the better the results, both immediate and remote. No operation is of any avail, and any will probably prove fatal in the most serious advanced cases, with widespread terminal degenerations, especially of the heart muscle, with irregular pulse, low blood pressure, and periodic attacks of delirium cordis (Kocher). The after-treatment is of the greatest importance. These patients should not be discharged from the hospital after operation to work out their own salvation, as they too often are. Careful supervision by a competent medical adviser should be carried out for several years at least.

Dr. James D. Heard, Pittsburgh: The severity of the cardiovascular disturbances in toxic goiter makes it important that patients of this type should be studied carefully in regard to disturbances of cardiac mechanism before they are submitted to operation. Alternation in force of ventricular systole should be sought for diligently, and when found in connection with a heart rate which is approximately normal, it is to be regarded as greatly increasing the gravity of prognosis in a given case. The administration of belladonna should not be a routine procedure. It should be remembered that belladonna in full dosage removes the inhibiting action of the vagus, and this result would be undesirable in cases in which the heart rate is already unduly accelerated. For like reason, the administration of atropin to guard morphin would be unscientific. Morphin requires no guarding. It acts favorably in these cases, partly through its action on the vagus, and it would be a distinct disadvantage to remove this inhibitory action in cases in which the heart rate is already accelerated.

Dr. G. M. Astley, Philadelphia: It is a question in my mind as to whether injections of boiling water should not be used first before ligation. The problem seems to be the throwing out of commission of a certain amount of gland substance. The boiling water will accomplish that. I have known cases in which, when boiling water was used, the subsequent surgical sections were very simple.

Dr. S. J. Waterworth, Clearfield: If we avoid the trachea, I believe we will have fewer bad symptoms following operation. As to operation following hot water injections, I have injected with hot water and know it renders operation much more difficult. There is produced a general thyroiditis. The tissues become matted together, and you have more difficulty in getting the goiter out.

Rectal Anesthesia in Thyroidectomy

Dr. Walter Lathrop, Hazelton: In the oil-ether rectal anesthesia the brain is not deeply narcotized, and the patient regains consciousness rapidly, while the sensation of pain is held in abeyance for a considerable time; the eye reflex is seldom lost, but muscular relaxation is complete. The method is very valuable where fear is a prominent element, as is the case in hyperthyroidism. The postoperative effects are much milder than after inhalation narcosis. In thyroidectomy, in which freedom from obstruction in the operative region is desirable, the rectal method is ideal. Also the patient can be anesthetized in bed and removed to the operating room and thus have no conception of what has occurred. This is a great aid in realization of the anociassociation method. I have used the method in 118 cases since June, 1914, with most satisfactory results.

DISCUSSION

Dr. John W. Luther, Palmerton: My experience with colon-oil-ether anesthesia is limited to forty-seven cases; thirty-six were abdominal operations in which complete muscular relaxation is of greater importance than in head and neck work. In twenty-two of my cases no additional anesthesia was required, and in eighteen of the remaining cases only a dram to an ounce of ether by inhalation was needed. The duration of operation varied from fifteen minutes to two hours. On account of the slowness in preparation, the method is not suitable when several persons are to be operated on in succession. One of my patients died of pneumonia seven days after operation; but this was a septic case, and the result cannot be attributed to ether. The narcosis is uniform from beginning to end.

Dr. W. Hersey Thomas, Philadelphia: My experience in operating on seventy-three patients under colonic anesthesia has convinced me of its value in selected cases. I have not found that rapid return to consciousness is the rule. Although the presence of some of the superficial reflexes would indicate a light anesthesia, the great majority of my patients were profoundly anesthetized. I have seen the anesthesia deepen after return of the patient to the ward, in spite of rectal irrigation. The conviction has grown that the liver, which bears the brunt of the attack in this method, is markedly affected, and that it is a toxic change in this viscus which prolongs the anesthesia. The return of consciousness is hastened by the introduction of saline solution. The patient should be kept under skilled observation for several hours after return to the ward.

Dr. Walter Lathrop, Hazleton: In abdominal cases we have had quite an experience, especially in miners having asthmatic conditions. If you start ether in these cases they choke, and must stop. These patients sleep perfectly under rectal anesthesia. I have seen very few who could not be aroused.

Surgical Treatment of Ascites

Dr. Robert T. Miller, Jr., Pittsburgh: Of five cases in which ascites was associated with cirrhosis of the liver, four were due to alcoholic or syphilitic cirrhosis, and the fifth almost certainly was due to malignant diseases. The patients varied in age from 18 to 60 years. Ruotte's operation was made in each case, four times unilaterally and once bilaterally (two sittings); in three cases general anesthesia was used, and in two local anesthesia. The only mortality was the malignant case. In all but the malignant case, abdominal paracentesis was necessary at frequent intervals before operation; after operation, the necessity for tapping the abdomen was absolutely done away with in two cases and all but eliminated in two other cases, while in the fifth case (malignant) the abdomen was not tapped either before or after operation. In one case operation (double) was followed by a decrease of the umbilical circumference from 110 to 97 cm., and an increase in average daily urinary output from 480 to 150 c.c. Of the four cases of cirrhosis of the liver, three were restored to self-support, and the fourth, a boy of 18, was advanced from a condition of invalidism to a position of helpfulness in the household. In no instance was any ill effect observed from drainage of the ascitic fluid directly into the circulation. The results obtained are encouraging; so good, in fact, as to warrant recommending a trial of this method.

DISCUSSION

Dr. James D. Heard, Pittsburgh: Statistics available as to the result of the Talma operation show that from 35 to

50 per cent. of cases of ascites due to cirrhosis of the liver may be cured by early operation. These statistics should be brought prominently to the notice of internists. The statistics of Ruotte, Soyesima and Miller indicate that venoperitonostomy is capable of yielding such favorable results that a further trial of this method is to be recommended strongly. Operative measures should be resorted to in the early stages of ascites before the patient has been subjected to the local irritation which results from frequent tappings, repeated withdrawal causing loss of protein, and general failure of patient owing to the continued presence of a condition which, in spite of repeated tappings, usually slowly progresses toward an unfavorable end.

Dr. J. E. Sweet, Philadelphia: In 1876, von Eck devised his operation, anastomosis between the portal vein and the vena cava. This operation has been applied only three or four times. Usually in true cirrhosis the portal vein is so tied up in adhesions that a true Eck fistula is not feasible. Dr. Edward Martin and I devised a modification of the Eck fistula consisting on an anastomosis of one of the large mesenteric veins with the iliac vein at the point at which they cross. That is a more positively curative procedure than the operation advocated by Dr. Miller, which amounts to continuous tapping.

Fulguration Treatment of Bladder Papilloma

Drs. A. A. Uhle and W. H. MacKinney, Philadelphia: Since November, 1911, when we first employed high frequency destruction, we have observed 51 primary neoplasms of the bladder. A diagnosis of benign papilloma was made in 22 cases, of papillary carcinoma in 3, and carcinoma in 26. High frequency destruction was employed in 19 of the benign papillomas, in 3 cases of papillary carcinomas, and 7 cases of infiltrating carcinomas. In all cases of tumor of the bladder, hemorrhage is the predominating and frequently the only early symptom. The bleeding is usually marked and ceases as promptly as it began. With three exceptions the monopolar Oudin current, generated from a Wappler coil, was employed and found perfectly satisfactory. The illumination was derived from a dry cell battery, and the spark from the circuit. General anesthesia is not necessary, a satisfactory local anesthesia being obtained by the use of novocain. In nervous patients or patients with a highly sensitive urethra, treatment may be facilitated by a hypodermic of morphin administered one hour previously. A clinical cure was based on freedom from symptoms, a clear urine, microscopically free from blood and pus, and the absence of any evidence of tumor by cystoscopic examination three months after the last treatment. Every patient was impressed with the possibility and danger of recurrences and advised to return at intervals of six months for cystoscopic examination.

DISCUSSION

Dr. B. A. Thomas, Philadelphia: To treat a papilloma of the bladder by any means other than high-frequency sparking or electrocoagulation must be regarded as a serious surgical error, poor judgment or selfishness. On the other hand, any form of endovesical treatment for a malignant growth, preeminently sessile carcinoma, provided it is curable radically, is the height of folly. My experience comprises not less than sixty-nine tumors, varying in size from a pinhead to masses almost completely filling the bladder. Almost invariably bleeding has been a prominent factor, but fortunately, as a rule, the first effect of electrocoagulation is hemostatic. A few patients have been so exsanguinated as to require preliminary supporting measures. In one case with 19 per cent. of hemoglobin, two transfusions were done before the treatment of the tumor of the bladder was undertaken. Without exception, cure has resulted in each case of papilloma, as well as in papillary carcinoma with a nondegenerated pedicle. In no case of sessile carcinoma or other malignant growth involving the bladder wall has cure been obtained. I have employed both the Oudin and d'Arsonval currents, and prefer the former. It seems to make little or no difference whether the current be degenerated by a static machine or a coil; the results are equally good with the latter.

Dr. John L. Laird, Philadelphia: The character of the bladder growth in relation to its amenability to this form of treatment is a serious consideration, the benign and the superficially malignant tumors being appropriate, the infiltrating malignant growths demanding immediate surgical intervention. The treatment of the various types of benign papillomas requires a selection of the kind of current to be used. The interval between treatments is important, and should be governed by three factors: the extent of bladder involvement, the type of current employed and the degree of reaction to the treatments. I wish to emphasize that all vesical papillomas are potentially malignant and, therefore, early diagnosis and eradication are of the utmost importance. High frequency destruction is beyond doubt the method of choice. For the same reason, after an apparent cure, each case should be followed for a possible recurrence. Some severe and obstinate cases require patience, and frequently the result is unsatisfactory and disappointing; but the majority respond promptly with a result little short of miraculous.

Dr. Edward Martin, Philadelphia: First in regard to the operative treatment of bladder tumors, by which I mean the cutting operation: Those who observe and wish to hear from patients notice, to their astonishment, that the old operating cystoscope gives very much better results in papilloma operation than does the open operation. Those who have a certain number of these papilloma cases have observed a widespread recurrence after the operation, and there seems no adequate explanation of this, except the disturbance caused by gross traumatism. We have, first, the lesson that the local nontraumatizing treatment is better, than instrumentation. The second point I wish to bring out is the innocuousness of this desiccation in the ordinary run of cases. For all practical purposes the majority of these people could attend to their ordinary business. They have no further discomfort and their lives are not materially interfered with. When the cystoscopist is unable to decide as to the malignancy or the benign nature of the lesion, I feel that this desiccation treatment should be tried and resort to our perhaps grosser methods follow.

Dr. H. M. Christian, Philadelphia: I want to emphasize the point made by Uhle and MacKinney that every so-called benign tumor of the bladder must be considered potentially malignant, and that a man with a so-called benign tumor in his bladder has to all intents and purposes dynamite in that bladder. In cases on the borderline, where there is a chance, the patient should be given the high frequency current. I want to emphasize again the importance of looking on sudden, inexplicable, rapidly disappearing hematuria, rapidly reappearing hematuria, with or without pain, as very significant of bladder tumor and requiring examination directly.

Dr. Alexander Randall, Philadelphia: I wish to call attention to the efficiency of electric fulguration of vesical papillomas (benign) and the recognition of the ultimate and potential malignancy of all such growths. In their early stage, therefore, while still benign, vesical papillomas represent a precancerous state. By their prompt and early recognition and treatment we shall be taking a definite step forward in the present campaign for the eradication of cancer.

Venous Thrombosis and Embolism

Dr. Angus McLean, Detroit: Although various causes have been assigned for thrombosis, our experiments have shown that an infection or toxin is necessary to its production. In our series of 1,610 laparotomies, thirty-three cases were followed by thrombosis or embolism. The embolus appeared on an average about two weeks after operation. The usual symptoms are chill and fever; if the obstruction is near the surface, pain is a prominent symptom. As for treatment, when once the condition has developed, absolute rest, warmth and measures to encourage the venous circulation are indicated. In the case of a thrombus, absolute rest should be insisted on as a precautionary measure against secondary embolism. This rest must be continued until the clot has had a chance to become thoroughly organized, a process which will usually take from three to four weeks.

1 *Form of Reflexes in Chorea. W. B. Swift, Boston.
2 *Study of Reflexes in Diagnosis of Nervous Diseases; Alteration and Absence of Umbilical Reflex in Diagnosis of Typhoid. H. C. Gordinier, Troy.
3 Case of Pituitary Disease (Acromegaly) with Polyglandular Syndrome. J. L. Bendell, Albany.

1. **Form of Reflexes in Chorea.**—Some authors believe in a single reflex in chorea—the knee jerk. Swift shows a reflex form that may appear during the elicitation of any of the normal reflexes. This form of reflex is really so peculiar as to amount to a sign of chorea of equal dignity with the respiratory signs of Graves and the new voice sign in chorea. The form of the reflex consists in an enhancing, retarding, or otherwise varying of the normal form of the reflex. It is described as the jerk-flop-wabble form of reflex response. It is any change of reflex motion caused by a choreic contraction. It occurs most frequently in the medium severe cases; and as a whole probably about one in five cases. It may be present in all the other normal reflexes.

2. **Diagnosis of Typhoid.**—Gordinier's study is based on the study of 111 cases certified to as cases of typhoid. Of this number four proved to be cases of la grippe, three of infectious endocarditis, four of pneumonia, one of pericarditis, and one of acute miliary tuberculosis. In only one of the above-mentioned cases was there the slightest alteration of the infra-umbilical reflex. This was a case of massive pneumonia that developed a suppurative peritonitis, the result of a deep-seated ulceration, with perforation of the ascending colon; and not until this perforation complicated the case did this reflex absent itself. The ninety-nine remaining cases were true cases of typhoid, and in eighty-six of these cases there was a definite alteration of the infra-umbilical reflex — 86⅔ per cent. Most cases of typhoid came in during the second or third week of the febrile reaction, and hence in sixty of these cases the reflex on admission was absent on both sides. In thirty-nine cases, however, that were seen during the onset of the febrile reaction it was noticed that during the beginning of the febrile reaction the reflexes were normal or slightly exaggerated, such as often occurs with the deep reflexes at the onset of multiple neuritis. But at the termination of the first week and the beginning of the second the reflex presented a characteristic alteration; that is, it was diminished first on the right side, then on the left, and in a day or two absented itself in the same manner first on the right and then on the left side. The reflexes remained absent until the temperature remained normal for several days when convalescence was well established. Then the reflexes reappeared, usually first on the side lost and then on the opposite side.

If the abdominal reflex is persistently absent after the febrile reaction has ceased, one should anticipate a relapse. In two cases of this type a definite relapse followed. In eight other cases with relapse, in which the reflex during the subsidence of the fever had reappeared, it again disappeared on the advent of the fever of relapse. Gordinier has never observed the infra-umbilical reflex absent in other febrile affections unless the abdominal cavity or peritoneum were directly affected. In three cases of paratyphoid responding at first to both the *Alpha* and the *Beta* types of the colon groups, it was absent on both sides until convalescence was complete, about two weeks after the evening temperature had remained normal. Gordinier has observed its absence on one side or other in six cases of pelvic peritonitis due to tubal disease, also in three cases of suppurative peritonitis due to perforative appendicitis, in one case of general peritonitis from ruptured gallbladder, in one case of perforation of a duodenal ulcer, and in a case of general suppurative peritonitis following perforation of the ascending colon. In thirteen cases of acute appendicitis without rupture it was absent only on the right side, reappearing again after operation. He has frequently found it present in scarlet fever and measles, and it was also present in fifteen cases of lobar pneumonia. In two cases of Laennec's cirrhosis of the liver with moderate ascites, it was present, and also in several cases of intra-abdominal tumors. It was found absent in three cases of multipara with large, loose, pendulous abdominal wall. Gordinier believes that this reflex is absent only on the rarest occasions unless some abdominal or serious peritoneal complication has ensued. He regards it as being highly suggestive or diagnostic of typhoid, or of the paratyphoid group.

4. **Neurotization of Paralyzed Muscles.**—Experiments performed by Erlacher on monkeys showed that it is possible to achieve a useful functional result within six weeks after stitching a severed motor nerve into a new point of the muscle. Also he was able by histologic examination to demonstrate abundant nerve fibers within the muscle. Experiments on guinea-pigs achieved the same results, this clearly proving that the point of entrance of the nerve into the muscle is nonessential, and that a paralyzed muscle can be sufficiently supplied from any other point with nerve fibers. Histologic examination showed that fine fibrillae had grown out from the thick nerve fibers and had formed motor end-plates on muscle fibers of perfectly normal appearance, with all the characteristic signs of accumulation of nuclei observed normally, though much thinner and finer. So that within the first four to six weeks it was possible to differentiate without error between the end-plates of the normal and the implanted nerves.

Erlacher advocates not to be satisfied with the simple neurotomy after Stoffel, because this method does not sufficiently protect against recurrences. It is better to follow Spitzy's suggestion and do a plastic operation, attaching the surplus nerve fibers of the spastic muscles to the overstretched and weakened antagonists, attempting on the one hand to strengthen the latter by supplying them with an excess of impulses from a center which is "overirritable," and, on the other hand, avoiding the danger of recurrence by attaching the severed nerve to another nerve track, or implanting it directly into another muscle. Erlacher was also able to establish that in order to supply a paralyzed muscle it is not necessary to use the prescribed nerve tracks, but that one can supply a muscle sufficiently by sewing a motor nerve directly into it at any point, thus producing a "neurotizing" function from that point.

From experiments Erlacher draws the following conclusions: First, the nearer the periphery the motor nerve was cut, the more rapid and certain was its regeneration; often in a short time (sixteen days) the complete regeneration of the motor end-plates takes place. Second, a dissected muscle flap can be sufficiently nourished and supplied with nervous elements from the underlying muscle. Third, degenerative changes occur rapidly in an isolated muscle flap even if it remains united only by connective tissue with a healthy underlying muscle, but no such high degree of degeneration is seen, as is seen in the case of poliomyelitic paralysis. Fourth, under the influence of the rapidly regenerating motor nerve a quickly progressive regenerative transformation takes place also in the muscle; thus after six weeks it might be considered as recovered in a functional and anatomic sense. Hence, it was evident that a paralyzed muscle can only achieve sufficient nervous functional capacity if its wounded surface rests widely on a healthy muscle.

Proceeding from these suppositions, in a further series of experiments Erlacher paralyzed a muscle by resecting its nerve, and sewed into it a broadly dissected centrally pedunculated flap from an adjoining muscle. These experiments confirmed that it is possible to supply a paralyzed muscle with nervous elements, namely, to neurotize it by way of another healthy muscle when the latter is broadly dissected and stitched into the former. Summarized, the following are the facts established: First, to provide a sufficient nervous supply for a paralyzed muscle it is not necessary to make an end-to-end anastomosis of the paralyzed nerve with a healthy one, but it is sufficient to stitch the healthy nerve directly into the muscle. Second, if no healthy nerve is at hand it is sufficient to use a flap of a healthy muscle for "neurotization"; this flap must be centrally pedunculated in order to provide sufficient innervation. Third, the point of implantation of the "*neurotiseur*" is less important.

5. **Neurotization of Paralyzed Muscles.**—Experiments as well as three clinical observations lead Steindler to believe that in the method of direct nerve implantation and muscle-to-muscle attachment, there is a possibility of a motor impulse being transmitted to the paralyzed muscle through physiologic channels. Neurotization of paralyzed muscle tissue from live nerve directly implanted seems probable, but neurotization of healthy muscle tissue by direct implantation of additional healthy nerve does not seem probable. At least Steindler found the speedy regeneration of the normal nerve and its end organs to be a barrier to the neurotization from a second nerve, or hyperneurotization, and although in one case it was possible to follow the nerve fibers as they entered the muscle tissue, still it was impossible to obtain muscle contraction from stimulation of this implanted nerve because of the preceding regeneration and restoration of the original nerve supply. In the three clinical cases cited a physiologic impulse is apparently acting on the paralyzed muscles, though Steindler cannot say as yet whether this actually means complete restoration of the nerve elements from the implanted nerve. He says that it is difficult to recognize the state of regeneration of nerve fibers in the microscope, but the finding of striated muscle fibrillae is surely suggestive of this possibility. But even in the event that the muscle-to-muscle attachment alone should be responsible for the impulse on the paralyzed muscle, which is not probable, this method would seem to be a good expedient to elicit cooperative muscle action.

6. **Operative Treatment of Osteo-Arthritis.**—The operative treatment of osteo-arthritic joints Brackett believes is applicable only: (*a*) when the disease is localized (monarticular, traumatic); (*b*) when it is the residuum of a process, which has been arrested. He cites cases.

7. **Painful Nontuberculous Joints.**—Davis is firmly convinced that the greatest cause of the persistence of pain in joints once injured or diseased is the irritation of repeated often slight traumatisms due to the movement of the parts. That this has not been generally recognized heretofore is due to the difficulty in successfully carrying out a treatment of immobilization. Davis advises absolute fixation as a cure.

14. **Schick Diphtheria Reaction.**—Levinson and Blatt tested 208 children. Of this number sixty were normal, fifty-five were afflicted with diseases other than diphtheria or tuberculosis, eighty-six were tuberculous or suspects on whom a Pirquet was done, six had been vaccinated a few days before the Schick test was applied, and one was a case of diphtheritic paralysis. Series 1 consisting of sixty normal children between the ages of 7 months and 9 years, gave 47, or 78.13 per cent., negative and 13, or 21⅔ per cent., positive. Sex played no rôle whatever in the result of the reaction. Age on the other hand, did. All the children under 1 year of age showed a negative reaction, the susceptibility increasing with advance of age. In Series 2, out of fifty-five children afflicted with diseases other than diphtheria and tuberculosis, 34, or 61.8 per cent., showed a negative reaction to the Schick test. Here, also, as in the case of normal children, sex exerted no influence. Age was a factor, all children under 6 months reading negatively. In Series 3 thirty-three children, suspects of tuberculosis, received the Schick simultaneously with the Pirquet test. They seemed to have no influence on each other, some children giving a positive Schick and a negative Pirquet and vice versa. In Series 4, out of thirty-eight children that received tuberculin treatment, sixteen were positive. The result, however, bore no relation to the reaction obtained from the tuberculin treatment.

15. **Abnormalities of Myocardial Function.**—There is little doubt in Hart's mind that every subject of paroxysmal tachycardia has a defect of the myocardium that must be seriously considered. The prognosis is most difficult. Some patients over a period of many years have attacks which incommode them but little and the attacks become less severe, less alarming, and in some instances disappear altogether. Some have only a few attacks before the fatal termination. Hart has never seen a case that was fatal until a number of attacks had occurred, nor has he found such a case reported in the literature. The condition of the heart in the intervals between attacks is important as an aid in determining the seriousness in the individual case. If at these times the heart shows no abnormality other than occasional extra systoles, there is no imminent danger. If, however, marked valvular defects are present, if there is evidence of an old inflammation of the pericardium, if there is a general arteriosclerosis, if extra systoles constantly occur at frequent intervals, and if the heart is embarrassed in maintaining an adequate circulation in the periods of slow rate, the paroxysms will rightly be viewed with much apprehension. The paroxysm is exhausting to the heart. If the myocardial damage is made evident by the attacks only, the heart will probably successfully carry this stress; if, however, other evidences of myocardial damage exist, the strain of the paroxysm is a far more serious matter. The patients who do particularly well are young subjects with no evidence of cardiac abnormality between attacks. Middle-aged and elderly individuals sooner or later invariably develop other evidences of myocardial insufficiency and, while they may have many and frequent attacks of tachycardia without serious manifestations, the ultimate outlook is less favorable.

The frequency and duration of the individual attacks do not seem to be important factors in determining the prognosis. Much more important is the severity of the attacks as estimated by the degree of circulatory embarrassment, cardiac dilatation, the congestion of lungs and liver and edema of the extremities. Attacks associated with unconsciousness should be viewed with gravity. With a history of a moderate number of attacks over a number of years in a young adult, with intervening periods of normal heart action, one may usually give a good prognosis. When the patient is more advanced in years and has paroxysms of increasing frequency and severity, and intermediate periods characterized by signs of cardiac insufficiency, the outcome of any particular attack is doubtful, the prognosis for the future is not good.

20. **Epilepsy of Intestinal Origin.**—Of the facts observed or elicited by Cornwall's study of this case, the following are among the more significant: The family history was negative. In the patient's previous personal history constipation appears prominently, with gastric and intestinal flatulence and discharge of foul gases from the bowel. There was a peculiar sensation experienced in the upper right quadrant of the abdomen, brought on by running, described as "feeling as a lump bumping up and down," which was sometimes accompanied by pain. For some months before the convulsive attacks appeared, the patient devoted himself closely to study and neglected ordinary amusements, social diversions and out-of-door exercise. The most significant physical findings were those revealed by the Roentgen-ray examinations, which showed a coloptosis, with the transverse colon in the pelvis; the ascending colon extending one and a half inches above the iliac crest, and the descending colon extending 3 to 4 inches above the iliac crest, notable dilatation of the terminal portion of the ileum, and insufficiency of the iliocecal valve; but no distinct obstruction anywhere in the *course of the gut, and no particular stasis except in the terminal* portion of the ileum. The constipation showed a tendency to persist unless relieved by laxatives.

The convulsive seizures resembled, in general, those commonly observed in epilepsy, but they showed considerable variation in character, intensity, duration and the occurrence of premonitory and subsequent symptoms. They occurred six times during the year 1913, and eleven times between Jan. 1, 1914, and June 1, 1914. After being put on a course of treatment which was aimed chiefly at relieving constipation and intestinal putrefaction, the attacks diminished greatly in frequency. One attack occurred seven days after beginning the treatment, and then there was freedom from the attacks for more than six months. During the remainder of the period of a little over a year, while under this treatment, four attacks occurred, which were milder and less typically epileptic in character than the former ones. Three of these four attacks occurred while the patient was occupied with his college work, and was getting an insufficient amount of sleep; and they took place while he was sitting at a table studying, instead of when lying down as before. The facts observed suggest the possibility of a toxic-exciting or mechanical cause of intestinal origin and they also suggest what seems to be the most promising line of treatment.

35 Pituitary Extract as Hemostatic in Hemorrhages of Lungs. M. J. Konikow, Boston.

33. **Effect of Rowing on Heart.**—The authors found that there is little difference in the size of the heart of men who have been rowing for two or four years and men who have been rowing over ten years. The hearts of these two groups are slightly larger than the hearts of a younger group who have not as yet participated in serious competitive rowing. These differences seem to be explained by the differences in age and development. The only conclusion drawn from this study is that prolonged participation in rowing under the system now in vogue at Harvard University and the Union Boat Club of Boston does not materially increase the size of the heart when the heart is sound at the beginning.

34. **Blood Pressure in Spinal Anesthesia.**—Smith claims that the blood pressure can be lowered as much by spinal anesthesia as by section of the cord in the cervical region. In his experimental work the greatest fall was caused by injection of the drug in the thoracic region, in which the vasomotor fibers which supply the splanchnic area leave the cord. This part of the vasomotor mechanism is the first affected by the drug when the injection is made in the lumbar region. The extent of diffusion of the drug within the dural sac appears to be influenced more by the bulk of the solution injected than by any other one factor. A given amount of drug in a concentrated solution diffuses less and consequently lowers blood pressure less than does the same amount of drug in a more dilute solution. The greatest effects on blood pressure were noted when epinephrin was combined with novocain. Entire fixation of the drug does not take place within twenty minutes after the time of injection. When a solution of greater specific gravity than spinal fluid is used, the extent of diffusion may be increased by gravity. Attempts to raise the blood pressure by the intravenous injection of pituitary extract or epinephrin gave only a transient rise.

50. **Spinocelled Cancers of Skin.**—There are, says Hazen, two varieties of prickle-celled cancer, a malignant type and a warty type, that will metastasize only under special circumstances. These growths always arise from abnormalities, hence many of them could be prevented, or at least operated on at an early date. Spinocelled cancers are apt to metastasize to the regional glands, even at an early date. The best results have come from the local removal of the growth, together with the radical removal of the draining

lymphatic glands. Any form of treatment which does not permit of the proper diagnosis and differentiation of the primary growth is to be deplored. At this point it would be well to point out that many basal-celled cancers can be clearly distinguished in the gross.

52. **Psoriasis Treated with Autogenous Serum.**—Fifty cases of psoriasis were selected by Trimble and Rothwell; thirty of these were given the serum treatments, the remaining twenty being used as controls. The controls were divided into two groups of ten each, one group being placed on 2 per cent. chrysarobin ointment, and the other on a 10 per cent. white precipitate of mercury ointment. An ointment of 2 per cent. chrysarobin was given to each patient taking the serum injections, after the sixth treatment, but so far as possible the injections were continued until the total number reached ten. In twenty-eight of the thirty patients receiving the serum injections, there was absolutely no change in the eruption before the salve was prescribed; after this time, resolution progressed with fair rapidity. The control cases furnished some interesting points. To ten of these was given 2 per cent. chrysarobin ointment, so as to compare the rapidity of action with and without the serum injections; ten also were put on the unguentum hydrargyri ammoniati, 10 per cent., to see how the rapidity of action compared with the weak chrysarobin applications. It has been almost a routine measure in the clinic to give all cases of psoriasis, at the first visit, the unguentum hydrargyri ammoniati. In a certain small percentage of mild or early cases this application would remove the lesions; if so, then the disagreeable staining, irritating chrysarobin would be avoided; if not, the case was put on the chrysarobin ointment. The controls using the white precipitate of mercury ointment acted about as was expected; some were benefited and some were not, but the comparison sought was decided. The mercury ointment was not to be compared in efficiency with the 2 per cent. chrysarobin.

The controls using the chrysarobin furnished some valuable information and caused the greatest surprise. First, the action of the drug was about the same in the control cases as in the serum group. If there was any difference, it was in favor of the control group; they seemed to progress more favorably and effectively than the injection cases; this may have been a coincidence due to individual tendencies. The surprising observation was that the 2 per cent. chrysarobin seemed to act quite rapidly and effectively and to produce dermatitis with the same frequency as the same ointment in 10 per cent. strength. The psoriasis lesions would vanish, leaving the same white areas and the same surrounding dermatitis as when a 10 per cent. ointment was used. In one or two instances a marked dermatitis was produced with the supposedly weak ointment. In one of the serum cases, a young woman, the 2 per cent. salve produced an intense dermatitis, the redness, heat and edema of the skin causing great tenderness on pressure, and being sufficient to cause sleepless nights.

65. **Treatment of Acute Epididymitis.**—The technic Walther has adopted is as follows: The scrotum is prepared aseptically as for any operation; the practice being to shave the skin, thoroughly cleanse the same with green soap and sterile water, and then paint the site of puncture with tincture of iodin. The affected testis is then firmly grasped with one hand, the epididymis to be punctured pointing uppermost, and the skin over the selected area of entrance of the needle is put on tension. A sharp-pointed, fairly large needle which is connected to a 10 c.c. record syringe, and which has been previously sterilized, is then thrust through the skin of the scrotum into the substance of the epididymis for one-half to two-thirds inch, and then the attempt is made to aspirate gently some of the seropurulent content. By withdrawing the needle slowly aspirating all the while, one will often succeed in obtaining fluid from the different levels in the gland when the same would not be gotten if the needle was held in only one plane. Usually two or three punctures at different points in the affected organ are made. The wounds are then sealed with a collodion dressing and a suspensory applied to the scrotum. Confinement to bed is not necessary. The only anesthetic used has been that of spraying locally the site of puncture with ethyl chlorid to freeze the part. As a rule, little fluid is withdrawn. The effect of the aspiration, however, becomes manifest by an almost immediate relief from pain, and within six to twelve hours the swelling in the gland and the fever have diminished considerably.

82. **Infantile Eczema.**—In speaking of the treatment of this disease, Cheney emphasizes that external applications are not to be considered first. First thought and consideration should be the nutrition of the child, and a careful inquiry as to the food which has been given will give us a clue to proper treatment. If it is a breast-fed baby, one may often find that it has been fed at frequent and irregular intervals,

perhaps every two hours, and the mother has an oversupply of rich milk. For such a baby endeavor to do two things; first, decrease the abundance and richness of the mother's milk, and second, cut down the baby's supply. For the mother, advise more exercise and a lessening of the quantity of food which she takes, omitting particularly milk, cream and the cereals. For the baby, prescribe regularity of nursing and long intervals between feedings. The baby should not be nursed oftener than once in four hours, and not allowed to stay at the breast too long. The food can be diluted by giving the baby 1 or 2 ounces of water or barley water just before each nursing, partly filling its stomach, and thus it will not take so great a quantity of milk. Some cases persist after all these trials. They are probably cases in which there is an intolerance for some ingredient in the mother's milk, and for such a wet nurse may be tried, or if one can make the baby fairly comfortable, worry along for a few months until the child is old enough for other food. For the bottle-fed baby, vary the food constituents to suit each case. Cases which still resist all such feeding often can be cured by using the so-called albumin milk.

93. **Experiences with Malt Soup.**—The method adapted by Southworth was to select from day to day those cases whose condition was most critical, and to employ for each infant, in making up its daily supply of food, the number of ounces of milk, or top milk, which it would properly receive in an ordinary suitable formula. To this, and the requisite amount of water, was added the malt soup extract and wheat flour, usually in the proportion of one level tablespoonful of each for approximately each 10 ounces of the total food. The mixture was brought slowly to a boil to gelatinize the starch, and was then strained, cooled and bottled. As a life saver, or at least prolonger of life, the malt soup mixtures proved successful in nearly every instance in which they were given. The prophecy made at the start that flocculent white and green stools would become smooth and brownish within twenty-four to forty-eight hours, was, as a rule, justified. Infants who seemed doomed, ceased to lose weight, and in many instances promptly showed moderate gains.

94. **Blood Coagulation in Infancy.**—Shaw and Williams made examinations in 108 healthy infants under 2 years of age by this method, and found the determinations were between one minute fifteen seconds and one minute forty-eight seconds, and the average coagulation time was one minute thirty seconds, which is a slightly shorter time than in adults. They used the coagulometer of Russel and Brodie, as modified by Boggs and described by Emerson, consisting of a moist chamber with a glass bottom which can be placed on the stage of the microscope.

96. **Reinforcing Paralytic Flail Joints.**—The main ideas in the plan of treatment employed by Bartow are an attempt to provide better opportunities than are contained in the available operative methods for relieving these forms of disability, and also their timely employment to lessen the amount of muscular deterioration depending on disuse of a limb. he purpose kept in view has been to formulate a plan conistent with use in both the early and late periods of residual aralysis and also in young patients if desired. The procedure does not mutilate the joint, and as it causes no interference with the muscle supply, does not jeopardize the chance of improvement or recovery by natural processes inasfar as this is possible. Ankylosis, unless desired, is not the outcome of this procedure, but limitation only. At the same time the procedure possesses a range in its application whereby its repetition will safely prove additional limitation of any required degree. In about 150 cases in which this plan has been used, there has been no mortality, and in no instance an infection of a joint. This plan, proposed by Bartow about three years ago, contemplates fastening the paralytic flail joint by means of paraffined silk strands, inserted within the joint, to limit motion and promote stability for weight carrying.

3 Paroxysmal Hemoglobinuria; Report of Case. E. Emrys-Roberts.
4 Congenital Dislocation of Right Foot with Almost Complete Absence of Right Fibula. E. M. Sympson.

1. **Acidosis in Diabetes.**—The chief practical result of the work done by Guy's Hospital during the past twelve years on the question of acidosis in diabetes has been the demonstration that analyses of the carbon dioxid in the alveolar air of the lungs afford an index of the degree of acidosis and a guide in treatment and prognosis. The authors show that in cases of diabetes there is a relation between the alkalinity of the serum and the amount of carbon dioxid in the venous blood; the two rise and fall together without being actually parallel. In the nondiabetic cases, which were taken for the purpose of control, the alkalinity of the serum ranged from twenty-fifth-normal to thirtieth-normal. They also determined the tension of the gases of the blood circulating in the body. The means of fifty observations on ten men are 5.57 volumes per cent. of carbon dioxid and 14.89 of oxygen; the maxima are 6.11 and 15.59, the minima 4.87 and 13.91. Diabetic patients may have alveolar pressures of carbon dioxid, which are within the normal limits, although they are passing large quantities of sugar in the urine. When there is acidosis the carbon dioxid falls, and in diabetic coma reaches as low a figure as 1 or 2 volumes per cent. If under treatment with sodium bicarbonate the patient recovers, the pressure of carbon dioxid may gradually rise to the normal level. Moreover, in diabetic patients, massive doses of sodium

bicarbonate may raise the pressure to a height beyond the normal range.

2. **Alveolar Carbon Dioxid Determinations in Treatment of Diabetes.**—The object of alveolar CO_2 determinations is to measure the severity of the acidosis. Hence, Poulton says, it is useless to apply the method he used when the urine, in a case of diabetes, gives a negative result with the nitroprussid test. Under these circumstances the alveolar CO_2 pressure will always fall within normal limits. However, when the urine contains acetone bodies, it is usually impossible from the nitroprussid or ferric chlorid tests alone, to say how severe the acidosis is. In any of these cases the alveolar CO_2 pressure is a sure guide. By its means cases can readily be divided into two categories: 1. The mild cases, in which the alveolar CO_2 pressure falls within normal limits; in these cases the prognosis with regard to coma is relatively good. 2. The severe cases in which the alveolar CO_2 is definitely lower than normal; here the utmost care must be taken to prevent the onset of coma. All the time the CO_2 is below normal the patient is, as it were, on the edge of a precipice, and any disturbance, such as sudden excitement or worry, or the administration of too rigid a diet, may push him over the edge.

In these cases the actual CO_2 pressure observed will give the measure of the danger. A value of 2 per cent. means that coma may supervene within twenty-four hours. A value of 3 or 4 per cent. is less dangerous; in the worst event, coma will not come on for at least two or three days. A sudden drop in the alveolar CO_2 is also of significance; it means that acidosis is increasing, and, though the immediate danger may not be great, there is always the possibility of a further increase until coma sets in. Again, it is possible to be misled if reliance is placed on symptoms alone, without determining the alveolar CO_2, because it not infrequently happens that the rapid onset of coma may be suspected from symptoms, even when the alveolar CO_2 still remains relatively high. It does not necessarily follow that the chance of averting coma is hopeless because a low CO_2 pressure is obtained. It may be kept off for a considerable time by judicious treatment.

17. **Trench Frost-Bite.**—The observations recorded by the authors were made on rabbits. One of the hind feet was shaved and the animal was then placed in a wide glass cylinder standing on a layer of earth which was kept dry or moist according to requirements. By this means it was found possible to reproduce in the rabbits' feet the edematous swelling characteristic of trench frost-bite. In the first place, it was found that when the mud was both wet and cold the swelling became marked in from two to three days. On the other hand, when the mud was kept dry the cold had much less effect. Constriction of the limb by means of a band of sticking plaster increased the tendency to edema in the feet exposed to cold. This effect was not obtained by a single band, but when the band was taken twice round the limb the cold produced edema more rapidly.

The effect of applying warm water (at 37 C.) to the foot after it had been exposed to the cold was to increase the edema markedly. The swelling was confined to the parts which were directly exposed to the cold; it was less marked in the hind foot which had not been shaved. The animal with a swollen foot could still walk with it, though there was a certain amount of limping. On the other hand, the evidence of anesthesia in the foot was indefinite. When the rabbit was placed in its cage in the animal house after an experiment, the swelling rapidly disappeared and it walked about normally after twenty-four hours. The microscopic examination of the tissues showed that the chief effect of the cold was on the blood vessels. The lumen was dilated and contained a certain amount of fibrin deposit; the endothelium of the intima was swollen; there was vacuolation in the muscle fibers of the media, and there was an increase in the number of cells in the perivascular tissue. In certain cases, and especially when the edema had been present for a longer time, there was a diffuse infiltration of the swollen tissue with leukocytes. The changes in the nerves consisted in edematous swelling of the axis cylinders, and this appeared to be merely a part of the general edema of the feet. There was no sign of degeneration of the myelin. The nerve cells in the cord were normal.

18. **Phenolization in Treatment of Gas Gangrene.**—In order, Mencière says, to prevent infection, the best means is embalmment of the wound. The technic is as follows: Long incisions, cleaning up the gangrenous cavity, removal of splinters and fragments of clothing, extraction of the projectile, usually a bullet or piece of shell. Protect the neighboring parts with cotton-wool and compresses, which should be as impermeable as possible, block any counter opening with a tampon, or defer making a counter incision until after phenolization. Hold up the edges of the wound with Kocher's forceps in order to form a pit. Fill the wound to the brim with a solution of crystals of 9 parts pure phenol, 1 part alcohol, and with small tampons swab out all its recesses. Allow this solution to remain in contact with the wound for one to one and a half minutes. Avoid cauterization of the surrounding skin. This requires some dexterity. Remove all excess of phenol with tampons and by gentle irrigation with strong alcohol to the amount of 3 or 4 liters (5 to 7 pints). Then at the same sitting, embalm with 150 to 200 gm. (6 to 8 ounces) of a solution consisting of 1 liter ether, 10 gm. each of iodoform, guaiacol, eucalyptol, 30 gm. balsam of Peru, and 100 c.c. 90 per cent. alcohol.

22. **Picric Acid as Antiseptic.**—Tidy found experimentally that a 0.165 per cent. solution of picric acid has the same bactericidal powers toward the culture of typhoid bacteria as has the standard 1 per cent. solution of phenol. Thus the Rideal-Walker phenol coefficient of picric acid is exactly 6.

been labeled neurotic or hysteric, as nothing to suggest gallstone disease can be discovered in them, but small amounts of sugar are found in the urine, and the assumption of pancreatitis explains the above symptoms. The gradual aggravation of the symptoms and the increasing amounts of sugar in the urine in one such case gave the warning for terminating the pregnancy.

There is one case on record in obstetric annals of necrosis of the pancreas following the puerperium, and surgeons have casually mentioned in a number of cases that the women had borne a child not long before. Some mention that the women had had "gallstone colics" before, but the biliary apparatus was found normal. There can be no question that acute and chronic gynecologic affections, entailing adhesions with the omentum or thrombosis in the veins of the omentum or mesentery, may lead to necrosis of the pancreas. This is especially liable to follow a gynecologic operation.

In conclusion, Prochownick states that the literature and his own experience confirm the close physiologic connection between the pancreas and the internal genital organs, but further research is needed in this line. Functionally, also, we can assume a connection between the pancreas and glucosuria in pregnant women and the severer forms of incoercible vomiting. The data already available warn the gynecologist of the necessity for special care in operating not to leave conditions at any point that might favor thrombosis or embolism in the veins of the omentum or mesentery.

68. **Liver Functioning in the Pregnant.**—Bauch applied the galactose alimentary test systematically to twenty-two pregnant women. The responses were constantly within normal range except in one case in which a pathologically high sugar content in the blood before the test increased under the galactose.

70. **Theoretical Explanation of Agglutination Test.**—Stuber describes his personal research on this phenomenon of immunization which, he is convinced, has to do with fats rather than albuminous substances. Testimony is accumulating more and more, he asserts, in regard to the unreliability of the agglutination test, and he was himself able to induce a positive agglutination response with the most heterogeneous bacteria. It was also positive in dysentery in Gaehtgens' research. There is, however, a specific agglutination titer, and precision in the diagnosis of typhoid can be obtained only when the highest titer of possible agglutination is determined for a large number of typhoid cases and an average taken as the standard to differentiate typhoid. There is much to sustain the assumption that the fats are the most amenable of all substances to chemical reactions. The albumin molecule seems to act merely as the transporting molecule for the chemically readily reacting fat cleavage products. The response to the agglutination test seems to be a quantitative specific process with a relative chemical identity of the bacterial cell.

72. **Serotherapy of Scarlet Fever.**—Reiss and Hertz used the mixed serum from several scarlet fever convalescents, injected it intravenously in large doses, and declare that their further experience with this form of serotherapy has fully confirmed its preeminent efficacy, actually life saving in many cases. The dose has to be at least 50 c.c. for children and 100 c.c. for adults. The injections have to be commenced before the fourth or fifth day to be promptly effectual. Ordinary serum sometimes produced the same effect as the convalescent serum, but this was not always the case, and hence it is not to be depended on. Normal horse serum seemed entirely impotent. They took the serum from the donors between the eighteenth and twenty-fourth days, after negative Wassermann tests and excluding tuberculosis and septic cases. About 100 c.c. of blood can be drawn for the purpose from older children and 200 c.c. from adults. The indications for this serotherapy are the severer toxic form of scarlet fever, the pulse small and irregular with cyanosis, delirium and restlessness. On the other hand, when the toxic condition is the result of secondary infection, this serotherapy is comparatively useless.

74. **Determination of Small Amounts of Mercury in the Urine.**—The test is based on precipitation of the mercury by means of basic iron acetate. The findings with this and other tests are tabulated for comparison in forty-two cases, all confirming the extreme delicacy of the test.

75. **Early Diagnosis of Tuberculosis of the Spine.**—Janssen comments on the fact that vertebral tuberculous lesions are so seldom recognized in an early stage. Irreparable damage is usually wrought before the disease process is suspected. Much is gained if the physician even thinks of the possibility of tuberculosis of the spine instead of ascribing the symptoms to rheumatism, neuralgia or lumbago. He relates two cases in which massage, etc., were applied for assumed lumbago with eventual disastrous results. In other cases a gravity abscess from a vertebral tuberculous process simulated appendicitis; appendectomy led to no relief, and not until several months later was the case explained by the manifest vertebral process. The tenderness in the cases of this kind was not at McBurney's point, but along the course of the ilio-inguinal nerve. On the basis of the mistaken diagnosis of sciatica, treatment was instituted in some by baths, electricity, etc., which directly aggravated the tuberculous process beyond repair. Pain in the back on long standing should suggest possible tuberculosis of the spine, or even slight discomfort in the back on standing quietly or sitting at table. This was the very earliest symptom in many cases, and suggested vertebral involvement when found in the afebrile tuberculous. When there is backache after a long walk the process is apt to be more advanced. The pain is felt at some point in the spine, with also discomfort at the upper and lower ends of the spine. These pains after walking may be referred to the region on each or one side of the spine, and they may be mistaken for pleurisy, or there may be a kind of girdle sensation; this strongly suggests vertebral disease. When it is located low down, there may be pains in the lower abdomen, predominantly in the ilio-inguinal region, which may also be tender.

Tenderness along the inner margin of the ilium and the farther course of the nerve is more characteristic than pain in the sciatic or other nerves. Pain and tenderness increase after long walking and, if the temperature rises, the picture of appendicitis may be deceptively simulated. He has only rarely encountered spasmodic contracture of the long muscles of the back in the early cases or pain in the spine when the head is struck. Roentgenoscopy is advisable in all cases, but is seldom very instructive in the early stages. Conservative measures are of little use unless supplemented by immobilization. He rarely uses a plaster cast in the early stages, preferring a sail-cloth stretcher and husk mattress, (*Hirsespreu*), moving the patient always on the stretcher. After an interval he has the patient lie prone, raising the upper part of the body a trifle to correct the tendency to gibbus. General heliotherapy is a useful adjuvant. A complete cure is usually realized in time in the majority of cases, and striking results have been obtained even in advanced cases with pronounced paralysis.

95. **Uterine Cancer.**—Prochownick here reviews his life work in this line, recalling the various phases of treatment through which this led him in the course of his long practice, from almost absolute therapeutic nihilism through the radical operative era down to the conservative era ushered in by radiotherapy. Between 1882 and 1910 he performed 328 operations in 536 cases of uterine cancer, and at the very least he has permanently cured 8 per cent. of the women. Further improvement must be along the lines of radiotherapy, in particular for the uterine cancers which develop so slowly and without symptoms that they are already inoperable when first seen.

96 *Recurring Tetanus. H. Brandt.

96. **Recurring Tetanus.**—Sick reported once a case in which the patient had three separate attacks of tetanus at six weeks' intervals and recovered. Brandt here reports the case of a young officer who developed tetanus after a shrapnel wound of the foot, and recovered, but was still confined to bed for seven weeks when a new and more serious attack of tetanus developed. The incubation period was long, both times, and the man recovered.

99 *Suprarenal Treatment in Nephritis. (Opoterapia surrenale e nefriti.) T. Silvestri.

99. **Suprarenal Treatment in Nephritis.**—Silvestri states that considerable work in the line of organotherapy in nephritis has been done in Italy. He here analyzes the results, especially with suprarenal treatment. Antonio gave small doses of epinephrin in thirty cases of scarlatinal nephritis in children, and with good results. Fede extols epinephrin by the mouth as a valuable aid in nephritis of any kind at any age, but says that the effect is more apparent in children, as the elasticity of the kidney tubules and glomeruli is greater, while the suprarenals are larger in proportion than in adults. All agree that the epinephrin makes up for the deficit from suprarenal insufficiency. Silvestri here reports some experimental research in this line and four clinical cases. His conclusions are that epinephrin is a most valuable aid in acute nephritis, but that it is of no use in chronic disease of the kidney, for reasons which he enumerates.

102 Cyst in Mesocolon of Boy of 9. (Cisti linfatica multiloculare del mesocolon in un bambino.) U. de Conciliis.

101. **Epidemic Meningitis.**—Ponticaccia recently had seven cases of meningitis and in six no benefit from antimeningococcus serum was apparent. Two women died, as also a boy of 11, and a girl. The disease was mild in the fifth and sixth cases and the children recovered. The seventh patient was a boy of 10 with extremely severe meningitis and a germ resembling, but not identical with, the meningococcus was isolated from his spinal fluid. No benefit was apparent from serotherapy or other measures, but prompt and permanent improvement followed intraspinal injection of 1 c.c. of hydrogen peroxid in a 20 per cent. solution. After injection of 5 c.c. of this fluid, the boy fell at once into a calm sleep as if a narcotic had been given, and slept for six hours, while the temperature dropped from 40.8 C. to normal for two days, but then rose again. It subsided anew under repetition of the injection, and the third day he was given 5 c.c. of a mixture of equal parts of hydrogen peroxid and distilled water, thus 2.5 c.c. H_2O_2. Recovery was soon complete.

THE EFFICIENCY OF VARIOUS ANTITYPHOID VACCINES *

WILBUR A. SAWYER, M.D.
Director of the Hygienic Laboratory of the California State Board of Health
BERKELEY, CALIF.

For over a year the California State Board of Health has been manufacturing at the hygienic laboratory the Gay-Claypole[1] sensitized antityphoid vaccine and distributing it free to physicians. Data cards are sent with the vaccine and physicians are requested to describe reactions and complications and to report any cases of typhoid fever in those who have been vaccinated. When the data cards are not returned, a follow-up postal card is sent. Under this system reports of several cases of typhoid fever in vaccinated persons were received soon after the beginning of the distribution. The investigation here reported was undertaken to determine whether these failures were peculiar to the type of vaccine distributed by the state board of health and also to arrive at a more accurate idea of the value of antityphoid vaccination in the civil population.

The literature on antityphoid vaccination gives little information regarding its value under the conditions of ordinary civil life. For armies there is a rapidly increasing mass of evidence. In five sets of statistics for antityphoid vaccination in the British army, both during the campaigns in South Africa and in selected test-groups of soldiers in India,[2] there were large numbers of unvaccinated men to serve as controls by indicating the extent of the exposure and the relative protection of the vaccinated men. Among the unvaccinated there were from two to seven times as many cases of typhoid fever as among the vaccinated.

Vincent[3] reports more remarkable results for various bodies of troops in the French army. The typhoid morbidity among those vaccinated with a polyvalent vaccine killed with ether varied from nothing to 0.18 per thousand men, while among the unvaccinated it ranged from 2.22 to 225.61 per thousand. In the German army in the Herero campaign in southern West Africa in 1904 to 1907 there were twice as many cases among the unvaccinated as among the vaccinated.[4]

Brilliant success with typhoid vaccination is shown in the experience of our own army,[5] the morbidity being reduced to 0.03 per thousand men with no deaths. An almost complete absence of unvaccinated men to serve as controls makes it impossible to state just how far this success is due to improvement in the vaccine and in the method of administration.

There are three important factors which determine how much vaccination will reduce typhoid fever in a community:

1. The efficiency of the vaccination, as shown by the degree of immunity produced in the individual.
2. The proportion of vaccinated individuals in the community.
3. The extent of the exposure to typhoid infection, especially of exposure other than simple contact with individuals within the community.

In analyzing the success of vaccination in our army we cannot give all the credit to the first factor, which depends largely on the kind of vaccine and the method of administration, and also on the power of the individual to respond, because like results are not being obtained by similar methods in the civil population in places where the other factors are unfavorable. In the army the second factor must play a large part, because almost all the men are vaccinated and most of the individuals with whom the soldier comes in daily contact are immune and therefore unlikely to develop typhoid fever and to expose him to contact infection. There is, therefore, little chance for typhoid fever to spread in the army through contact even if it should in rare instances gain entrance to a body of thoroughly vaccinated troops. In the civil population we find that most of our failures are in persons who have lived in the same household with typhoid patients, who have nursed typhoid patients, or who have been exposed to some heavily polluted common food or water supply. The third factor is favorable in the army, especially in time of peace, as heavy and wholesale exposure is being prevented by scientific control of food and water supplies and of the general sanitation of camps and barracks. It is obvious that we cannot expect results similar to those in our army among the civil population where the percentage of the population vaccinated is small, and the exposure to contact infection correspondingly increased, and where there is often serious neglect of the supervision of public water, milk, and food supplies.

In the civil population, nurses have been more generally immunized than any other class. The exposure of nurses is much greater than that of the general population. Joslin and Overlander[6] have estimated that a hospital nurse is about eight times as liable to contract typhoid fever as the ordinary citizen. Various reports on the immunization of nurses give morbidities in the vaccinated ranging from nothing to 10.7 per cent. and corresponding morbidities in the unvaccinated varying from 11.4 to 35.8 per cent.[7, 8]

In epidemics, immunization of the general population has been resorted to frequently. Vincent[3] reports two epidemics, comprising a total of 712 vaccinated persons with no cases, and 2,793 unvaccinated with a morbidity of 44.4 per thousand. Townsend[7] reports an epidemic in Torrington, Conn., where there was one case of typhoid among 400 vaccinated persons. In the Sloane Hospital in New York, in a food-borne epidemic[9] due to a typhoid carrier, there were seven cases (15.9 per cent.) among 44 persons who had been vaccinated with various makes of typhoid vaccine at various lengths of time before exposure. Among 30 unvaccinated persons there were six cases (20 per cent.). Spooner[10] reports a water-borne epidemic in which sixty-five persons were exposed, of whom 29 were vaccinated during the outbreak. Among the vaccinated, one case occurred immediately after the first inoculation (3.4 per cent.). Of the unvaccinated 19 were still well at the time of the vaccinating, and five of these (26.3 per cent.) developed typhoid fever. Wade and McDaniel[11] report an epidemic in an institution, one month after the completion of vaccination of the inmates, wherein 1,396 vaccinated persons had 37 cases of typhoid (2.6 per cent.) with 3 deaths, and 304 unvaccinated had 16 cases (5.2 per cent.) with 2 deaths.

There are many reports of vaccination after epidemics, but in a considerable number of them judgment of the efficacy of vaccination is clouded by the fact that while the immunization was being performed other measures were taken to stop the epidemic, for example, the chlorination of a polluted water supply.

Statistics of vaccination among the general public, in the absence of epidemics, are meager. A total record of 26,376 such vaccinations was collected from the literature, with 9 subsequent cases, or 0.34 per 1,000. Most of these were reported in an incidental way that led to the conclusion that no special inquiry had been made to discover cases among the vaccinated.

In a small town in Kentucky[12] there were five cases of typhoid fever in persons who had, within eighteen months, been given vaccines made by at least four different commercial laboratories. About 1,000 persons in the town had been vaccinated. Russell[13] reports absence of cases in 359 vaccinated children. Among 11,772 vaccinated employees of the Canadian Pacific Railway on the western lines there were only four cases and one death.[14]

In the literature the results of vaccination, varying from apparently complete protection to almost none, bring home the fact that the immunity is relative, and that the severity of the exposure determines to a large degree whether the immunized person will escape. Vaccination seems to be more effective against infection from a slightly polluted water supply or the ordinary contacts of our daily life than against infection from a heavily infected milk or food supply or from continuous close contact with an acute case of typhoid fever.

THE CALIFORNIA STATISTICS

To obtain information regarding the results of antityphoid vaccination in the civil population of California, a questionnaire was sent to 2,400 physicians. Replies were received from 815, and 218 of these had administered antityphoid vaccine to 8,124 patients.

In Table 1 are given the statistics so collected regarding failures to prevent typhoid fever. They are classified according to the type of vaccine and the manufacturer. All cases reported as typhoid fever and occurring at least thirty days and not more than two and one-half years after the first dose of vaccine are recorded as true failures.

In Table 1 the letters A to E represent well-known commercial biologic laboratories. The letter F represents a municipal laboratory. In the beginning of the table are shown the statistics for the Gay-Claypole vaccine[1] manufactured and distributed at first by the department of pathology of the University of California, but after April 1, 1914, by the hygienic laboratory of the state board of health. The vaccine was made from five virulent strains recently isolated in California, and was sensitized, killed with alcohol, dried, ground, and suspended in weighed amounts in physiologic salt solution. The water-soluble substances were then removed and the sediment was again dried, weighed, and suspended. In the earlier lots of vaccine this last step was not a part of the process of manufacture, and five of the persons who later devel-

oped typhoid fever received this earlier vaccine. One of these five persons received a vaccine made from a single strain instead of from the five used in the present method.

The firm A which manufactured the greater part of the unsensitized vaccine used in the cases here reported on followed in essentials the United States Army method of manufacture and used the same typhoid culture (Rawlings).

In Table 2 are shown the intervals between the administration of the first dose of vaccine and the onset of typhoid fever in those vaccinated.

In using the table it must be kept in mind that the failures do not in all instances belong to the groups of vaccinations reported. All vaccinations reported, in answers to the questionnaire, as administered up to April 1, 1915, and all failures reported in these answers or afterward by letter up to June 21, 1915, are included in the tables without regard to whether the failures belonged strictly to the particular groups of vaccinations included in the answers to the questionnaire. In some cases the failures were reported by physicians other than those who did the vaccinating, and reports of all the corresponding vaccinations could not be obtained.

In determining whether cases were true failures the interval of time was counted from the date of the first dose of vaccine, because the methods of administration were not alike. The vaccine distributed by the state board of health was given at intervals of two or three days, while most of the other kinds were administered at intervals of ten days.

The basis for determining the diagnosis was in most cases not entirely satisfactory, especially as a positive Widal reaction is not proof of the diagnosis of typhoid fever in a vaccinated person. In all cases the symptoms were regarded by the attending physician as those of typhoid fever. In six of the patients who had received vaccine from the state board of health or the University of California a culture was obtained from the blood or at necropsy and in each case the organism obtained proved to be the typhoid bacillus. Blood cultures demonstrated the presence of the typhoid bacillus in the blood of three of the patients who had received the vaccine of Manufacturer A. In a few cases agglutination tests of the patient's serum were made with paratyphoid A and paratyphoid B bacilli, but with negative results. In a number of cases the diagnosis was strengthened by the fact that there were records of positive Widal reactions in unvaccinated patients in the same group of cases of typhoid fever.

TABLE 2.—INTERVALS BETWEEN THE FIRST DOSE OF VACCINE AND THE ONSET OF TYPHOID FEVER

Manufacturer	Interrupted Vaccinations, Two Doses Only	Early Cases 1 to 30 Days	True Failures				
			30 to 60 Days	2 to 6 Mos.	6 to 12 Mos.	12 to 30 Mos.	Totals
State Board of Health and University of California	1 (17 mos.)	10	6	4*	4	7	32
United States Army	....	...	....	..	...	1	1
A...............	1 (31 days)	8	4	3	5	3†	24
B...............	....	...	....	1	1	1	3
C...............	....	...	....	..	...	1	1
Total.........	2	18	10	8	10	13	61

* Includes one case completely vaccinated twice, once fourteen months, and again three months before the onset, and infected in a laboratory.

† One case, a nurse, vaccinated sixteen months before the onset, gave a history of having had typhoid fever twelve years before.

In Table 3 are shown estimates of the severity of the attacks of typhoid fever in the cases classed as true failures of the vaccination.

EXTENT OF EXPOSURE

The extent of exposure of the vaccinated persons was so very much greater than the average exposure of the citizens of the state, that in spite of the protection due to the vaccination, the typhoid death rate among vaccinated persons was considerably greater than the typhoid death rate for the state taken as a whole. This is due to the fact that most of the vaccine is sent to the parts of the state having the most typhoid fever and at the seasons of greatest exposure, when the appearance of cases warns the public of the danger of infection. The unusual extent of exposure is indicated by the fact that 824 of the vaccinated persons were nurses, most of them in charge of typhoid cases; 953 were vaccinated in the presence of typhoid fever epidemics; 28 were physicians; 15 were workers in bacteriologic laboratories; and 608 were members of households in which there were acute cases of typhoid fever. Among the 41 true failures, the vaccinated persons were exposed as follows: In 7 cases they received their infection from acute cases of typhoid fever in the same households; in 8 cases they were nurses in charge of cases of typhoid fever; in 2 cases they were bacteriologists working with virulent typhoid cultures; in 6 cases they were exposed to polluted water in water-borne outbreaks; in 5 cases they were exposed in a milk-borne epidemic; one case was that of a physician; and in 12 cases no special history of exposure was obtained. The exposures were similar in the cases of failure after the use of the sensitized and of the unsensitized vaccines. Unfortunately there is no way of estimating with any approach to exactness how many of the vaccinated persons would have developed typhoid fever if not vaccinated.

TABLE 3.—SEVERITY OF TYPHOID FEVER IN FORTY-ONE CASES CLASSED AS TRUE FAILURES

Manufacturer	Mild	Moderate	Severe	Hemorrhage	Perforation of Intestines	Death
State Board of Health and University of Calif.	12	3	6	2	2	2
United States Army	...	...	1			
A..................	4	4	7	1	0	2
B..................	...	3				
C..................	...	...	1			
Total...........	16	10	15	3	2	4

The extent of the exposure seems to be one of the most important of the factors which determine whether or not a vaccinated person will develop typhoid fever. In a food-borne outbreak like that at the Sloane Hospital in New York[9] vaccination seems to give inadequate protection, while in the more usual exposures of less severity, we can expect a considerable degree of protection. An instance in which vaccination was apparently of little value is furnished by a recent milk-borne typhoid epidemic in California. On the milk-route under suspicion there were 643 persons, of whom 17 had previously received the antityphoid vaccine distributed by the state board of health. There were 23 cases in the outbreak, 5 in vaccinated persons (three in one family), and 19 in unvaccinated people. Considering the outbreak by families, we find that there were 76 nonvaccinated families, 17 of which had typhoid fever in at least one person, and 7 vaccinated families, two of which had typhoid fever.

In a recent outbreak due to the drinking of water from a polluted well, out of twelve cases there were two in vaccinated persons. One had received the state board of health vaccine and the other had been given the vaccine of Manufacturer B.

Under the heavy exposure to typhoid fever which occurs in the civil population in various parts of the United States such occurrences as the above will take place from time to time and give rise to a distrust of typhoid vaccination unless more exact information is furnished regarding typhoid immunization in the civil population.

COMPARISON OF THE EFFICIENCY OF THE VARIOUS VACCINES

From the table it would appear that the Gay-Claypole vaccine has greater efficiency, measured by the lower percentage of true failures, than the unsensitized vaccines considered as a group. This is not shown beyond question by the facts at hand because the two sets of figures are not exactly comparable. The methods of distributing the vaccines were different, with the result that more of the Gay-Claypole vaccine than of the unsensitized varieties was used in large groups of people, as in lumber camps and institutions. Another possible source of error is the fact that a large part of the Gay-Claypole vaccine was distributed as late as the summer of 1914 and a certain number of failures are still to be expected in the vaccinated persons reported in the questionnaire. A number of additional failures would also be expected in the persons reported as vaccinated with the other makes. It is, therefore, out of the question to draw any definite conclusions regarding the superiority of one vaccine over another, on the basis of the figures available, but the statistics seem to indicate that there is no great difference between the principal types, and that the reported failures of the vaccine manufactured and distributed by the state board of health were not due to inferiority of the vaccine issued, but rather to limitations common to the several types of vaccine administered to the American public.

REACTIONS AFTER ANTITYPHOID VACCINATION

The severity of the reaction, as valued by the physicians who returned the questionnaire, is shown in Table 4. Observations regarding 2,695 vaccinations of university students and inmates of institutions with the Gay-Claypole vaccine by two physicians were excluded so that the figures might fairly represent a composite of the opinions of a large number of physicians. The fourth column in the table shows how many persons had reactions sufficiently severe, in the opinion of their physicians, to warrant their staying in bed for at least half a day. The classification of reactions as slight, moderate, and severe was intentionally left entirely to the physicians making the reports in order to find out their opinions regarding the amount of annoyance caused by the combined local and general reactions rather than to obtain exact observations on the phenomena. The question of severity of reaction is important when it comes to persuading the public to submit to vaccination in large enough numbers to make an appreciable reduction in the morbidity from typhoid fever.

It will be seen that the estimates of the severity of the reactions are almost alike for the sensitized and unsensitized vaccines. It was expected that the sensitized vaccines would cause distinctly less discomfort. Similar results have been obtained by E. S. Kilgore, in a series of observations, as yet unpublished and referred to here through his courtesy. Observations were made by Kilgore on the reactions of eighty-five subjects, vaccinated in four nearly equal groups. Two groups received the United States Army vaccine, obtained through the courtesy of Captain Henry J. Nichols, and two groups received the Gay-Claypole vaccine manufactured by the hygienic laboratory of the state board of health.

Of each pair of groups receiving the same kind of vaccine, one received the vaccine at two-day intervals, and the other at ten-day intervals. The reactions were measured mathematically on the basis of temperatures and measurements of the size of the local reddened area and the slight increase in circumference of the inoculated arm. The vaccines were used in the dosages recommended by their manufacturers and these were not exactly alike. Within the limits of Kilgore's tests and our inquiry no definite diminution of reaction due to sensitization was determined, unless this is indicated by the smaller number of persons (Table 4) who were sick enough to go to bed after receiving the sensitized vaccine.

TABLE 4.—REPORTS OF REACTIONS IN 5,429 VACCINATIONS

Kind of Vaccine	Not Specified	Absent		Slight		Severe		Necessitating Stay in Bed	
		No.	%	No.	%	No.	%	No.	%

CONCLUSIONS

1. Antityphoid vaccination is meeting a severe test in the civil population because the vaccine is most used where the exposure is greatest, and because only a small proportion of the people are vaccinated.

2. In California an inquiry has shown that the true failures were 5.0 per thousand vaccinations reported, and the deaths from typhoid fever were 0.49 per thousand. The total number of vaccinations reported was 8,124.

3. The percentage of failures indicated a slight advantage for the Gay-Claypole sensitized vaccine over the unsensitized vaccines, but the superiority was not conclusively demonstrated as the different sets of statistics were not exactly comparable.

4. There is little difference between the vaccines, sensitized and unsensitized, in common use in California with regard to the severity of reactions after inoculation.

5. If widespread and severe exposures are prevented by better supervision over public water, milk, and food supplies, vaccination can be depended on to diminish greatly the residual typhoid fever, especially if a large enough proportion of the people are vaccinated to reduce contact infection to a minimum.

ABSTRACT OF DISCUSSION

Dr. George E. Ebright, San Francisco: The interesting part of Dr. Sawyer's paper consists in his comparison between the use of vaccine in the army and in the civil population. There are three things which we, as clinicians, always naturally bear in mind and consider in giving typhoid vaccine to a patient. First, there is the degree of immunity that will be accomplished. As Dr. Sawyer says, we are not able at present to establish a conclusion from that comparison. Second, is the duration of the time required for the patient to receive a complete vaccination. The sensitized serum has the advantage of requiring a shorter period of time for administration. Then there is the matter of suffering and reaction which the patient will have to undergo. There again we are not able to come to a conclusion. But there are a number of things that arise for comparison between the army and the civil population. There are in civil life a number of things that do not obtain in the army. The civil practitioner has to deal not with the healthy soldier, subject to repeated physical examination in addition to the examination which he undergoes before he joins the army, but persons as well who may be suffering from any of the chronic diseases, such as tuberculosis. From my own experience I am very loth to give antityphoid vaccine to a person with the least degree of active tuberculosis. I have seen three cases in which the reaction was unusually severe in comparison with nontuberculous people. It would be premature, however, to come to a conclusion at the present time regarding the relation of a vaccine reaction against typhoid and tuberculosis, but inasmuch as the question is still undecided, it is the part of wisdom to be conservative. Finally, it is desirable to be mindful in making comparisons between army vaccine and sensitized vaccine of the possibility of army encampments being under better general sanitary conditions and being less subject to the danger of infection than is the case in civil practice.

Dr. H. J. Nichols, San Francisco: Dr. Sawyer's paper gives just the sort of results that I personally expected to see in the army in the course of a year or so after vaccination was introduced. I hardly expected that our results would be as good as they have been, but they have continued to be remarkable. The most recent statistics are just as good as they have been for the last three or four years. In other words, up to 1910, since 1904, we had been having between 200 and 300 cases of typhoid a year. During the Spanish War our rate was very high, but it dropped to a minimum of the number stated. Then came the results of vaccination. It is often said that sanitation has had a great deal to do with our results. I beg to differ from that opinion. I am somewhat familiar with conditions in the army, and I can say emphatically that sanitation has made no unusual advance since 1910 in the army; there have been no radical changes. Since 1910 and 1911, when vaccination became compulsory, our rates have dropped remarkably. Last year (1914) we had seven cases of typhoid fever. Four of these were in recruits who were taken into the army during the incubation period of typhoid. Three had been vaccinated, one five years before the attack, one had two doses two years previously, and one, three doses two years previously; but the majority of our cases are now in recruits who are taken in during the period of incubation. In a week or two after they enlist some men develop typhoid fever. Sometimes they have had one inoculation.

The fact is that our results are just as good today as they were when typhoid vaccination was first impressed on the public as being of great value. We have had no such bad luck as Dr. Sawyer reports in California. I do not pretend to say what his results are due to, but I do feel like emphasizing the fact that our vaccine is made with great care. It is a very simple matter, but it is made according to definte principles and they are rigidly adhered to. It is not an experiment with us any more. It is too valuable to experiment with, and we do not allow any changes to be made.

Another thing, we do not allow any vaccine to be used after four months. A great many of the commercial houses are allowed by law to put a year's limit on the vaccine. I do not know what effect this may have had in Dr. Sawyer's results. Again some persons receive only one dose or two. Our men take three doses, or they hear from us. All these factors are to be considered. Of course we are all in the same boat and the same principles must hold inside or outside of the service. I do not feel, however, that the explanations which are given for our success, such as lack of exposure, etc., are at all conclusive. Our men certainly are subject to the same infection that anyone is. Our soldiers go down town and go into restaurants, and everywhere they are subject to the same contamination as any other citizen. I cannot help believing myself, personally, that our vaccine is somewhat superior to the vaccines in general use. At any rate, the fact is that we have not had any such setback as is mentioned by Dr. Sawyer.

Dr. E. S. Kilgore, San Francisco: It is unfortunate that it was not possible to obtain reliable returns from another 8,000 unvaccinated subjects living in the same communities and under the same conditions as those included in this analysis. They would be the only group with which it would be fair to compare these results, and for reasons given in the paper they would undoubtedly have shown a much greater morbidity than the population at large. As it stands, the sensational fact which will stick in the mind of the ordinary reader is that there is actually more typhoid fever among the civil population who have received antityphoid vaccination than among those who have not. This impression will be false and dangerous unless the reasons for it given in the paper are duly appreciated. A factor not mentioned by Dr. Sawyer which may account for some of the morbidity among vaccinated subjects is the feeling of security which they have and the consequent relaxation of hygienic measures they would otherwise employ. The feeling has been widespread that antityphoid inoculation is a sure preventive, and the individual who considers himself already safe will not take troublesome precautionary measures. Therefore, an important practical lesson to be taken from this paper is that whenever we immunize people against typhoid fever (or any other infection) particular pains should be taken to make them understand that the protection conferred is not absolute and does not remove the necessity for ordinary hygienic precautions. In view of the presumable necessity of vaccinating every two or three years in order to maintain protection against typhoid, the question of relative severity of reactions following subsequent vaccinations has some importance. Some have been restrained from revaccination on account of the prevalent idea that later vaccinations produce greater discomfort than initial ones. Our experience at the University of California Hospital is that this is not true about as often as it is true, and that the average reactions from first and from later inoculations is practically the same.

Dr. L. B. Wilson, Rochester, Minn.: At the meeting of the Colorado State Medical Society last September, Jolley reported the results obtained by the use of typhoid vaccine in the National Guard while encamped during a strike in immediate proximity to a village in which a large number of cases of typhoid were occurring among private citizens. I do not remember the exact figures, but my impression is that the results were excellent, though there was abundant opportunity for the vaccinated men to become infected.

Dr. W. A. Sawyer, Berkeley, Calif.: I believe with Dr. Nichols that antityphoid vaccination was a very important factor, perhaps the most important single factor, in the astonishing success in the reduction of typhoid fever in the army. If it is claimed that the vaccine used in the army is superior to the vaccines manufactured by commercial houses which follow in their way the methods of the army laboratories, I wish it could be arranged that a large amount of the army vaccine, say enough for 10,000 people, could be distributed for use in the civil population of California. Then we should soon know whether the vaccine of the army is more efficient than the material now in use. If it is, the fact should be ascertained as soon as possible, so that the public will receive the most efficient antityphoid vaccine which can be manufactured.

THE CHOICE AND TECHNIC OF THE ANESTHETIC

ARTHUR DEAN BEVAN, M.D.
CHICAGO

It is the purpose of this paper to analyze the many existing methods of anesthesia with the object of determining if possible in a judicial way what anesthetics should be selected and what technic should be employed in a general surgical clinic. In making this analysis and in arriving at conclusions, we have been controlled by certain requirements: first, the safety of the patient; second, the comfort of the patient; third, the efficiency of the anesthetic agent; fourth, control, avoiding anesthetics which cannot be withdrawn with the first appearance of danger; fifth, the simplicity and general adaptability of the method; sixth, after-effects on blood tissues and viscera; seventh, complications, vomiting, etc., and eighth, effects on immunity against pus organisms, pneumococci, etc.

This study is based on the special interest devoted to this subject in my own clinic by myself and assistants, Drs. Isabella C. Herb, Hamburger and Ewing, Evarts Graham, B. F. Davis, and F. B. McCarty, on pieces of laboratory research which we have carried on, on observations made in the clinics of others both in this country and abroad, and from a study of the literature. The last ten years have been very active ones in the field of anesthesia. New and better means of local anesthesia have been introduced. The use of nitrous oxid has been gradually extended, especially in this country. Complicated apparatus, mixtures and sequences have been widely employed. The use of scopolamin and morphin and various substitutes for morphin, pantopon, narcophin, etc., have been given an extended trial. The intralaryngeal method has been developed by Meltzer and Auer. Spinal anesthesia, nerve blocking, and intravenous and rectal anesthesia have enthusiastic supporters, and have been employed in large series of cases. We have during this period seen in this country the gradual development of the trained anesthetist as a member of the surgical team. So much work has been done that it would seem that we have at hand enough evidence to determine what are the best and safest anesthetics, and in what particular fields each should be employed. Such an analysis would necessarily cover a very wide field, and in this brief paper it will be possible to present simply the essential facts of this study of each of the agents and the methods.

I began this study with the intention of securing for my own clinic methods of anesthesia which would cover fully the entire surgical field, which would be the safest, most efficient, the most satisfactory to both patient and surgeon, the simplest and least complicated. I desired also to find anesthetics which could be adopted and employed by medical men generally, as my clinic is a teaching clinic for medical students, and part of their instruction is the giving of anesthetics. From this standpoint I have analyzed the following:

1. Chloroform.
2. Ether.
3. Nitrous oxid gas.
4. Scopolamin and morphin.
5. Spinal anesthesia.
6. Blocking.
7. Infiltration.
8. Intravenous, general and local.
9. Intrarectal.
10. Intratracheal.
11. Intrapharyngeal.
12. Mixtures.
13. Sequences.
14. Anociassociation.

In each instance we have analyzed these agents and methods from the standpoint of:

1. Safety.
2. Comfort.
3. Efficiency.
4. Control.
5. Simplicity and general adaptability.
6. After-effects on blood and tissues and viscera.
7. Complications, vomiting, etc. Paresis of bladder and bowels.
8. Effect on immunity to pus organisms, pneumococcus, etc.

As a result of this study I submit the following brief summary:

CHLOROFORM BY INHALATION, OPEN DROP METHOD

1. Safety: The most dangerous of all inhalation anesthetics. Deaths from one in 1,000 to one in 3,000 on the operating table.

2. Comfort: A most agreeable anesthetic to the patient.

3. Efficiency: The most efficient anesthetic. Anesthesia and relaxation profound and complete.

4. Control: The anesthetic can at once be stopped on the appearance of danger signals, but the chloroform already in the system cannot be rapidly eliminated, and the effects persist for a considerable period. The margin between the required anesthetic dose and the toxic dose is too narrow for safety.

5. Simplicity and general adaptability: All that could be desired.

6. After-effects on blood tissues and viscera: Reduces hemoglobin. Produces often what is now generally recognized as late chloroform poisoning with fatty degeneration of liver, kidneys and muscle tissue which is usually fatal.

7. Complications: Vomiting in about one third of the cases. Lung complications and nephritis in a small percentage.

8. Effects on immunity: Reduces resistance against pus organisms, pneumococcus, etc.

Conclusion.—Because of its efficiency, comfort and simplicity it has probably been employed more generally the world over than any other anesthetic, possibly more than all other anesthetics combined. And yet the time has come when chloroform in spite of its many advantages should be absolutely and finally discarded because of the huge mortality attending its use both on the operating table and the late chloroform deaths, and because we have for all classes of surgical cases efficient and much safer agents. It is possible that in military surgery chloroform may still find a legitimate place.

ETHER BY INHALATION, OPEN DROP METHOD

1. Safety: The safest anesthetic agent known for prolonged anesthesia. Deaths from one in 5,000 to one in 10,000.

2. Comfort: Not an agreeable anesthetic to take, especially by the closed methods; much more agreeable in expert hands by the open drop methods.

3. Efficiency: Very efficient; complete anesthesia and relaxation can be obtained.

4. Control: The anesthetic can be stopped on danger signals, and the agent fairly rapidly eliminated if necessary under artificial respiration. The margin of safety between the anesthetic dose and the toxic dose is wide.

5. Simplicity and general adaptability by the open drop method is all that could be desired.

6. Reduces hemoglobin, slightly increases coagulability of the blood, and produces few if any cases of injury to liver, kidneys and muscle tissues such as occur from chloroform.

7. Vomiting in from 30 to 40 per cent. of cases. Lung complications and nephritis in a small percentage of cases.

8. Reduces slightly resistance against pus organisms and pneumococci, etc.

Conclusions.—Ether by the open drop method is the safest general anesthetic known for producing prolonged anesthesia. It should be today the standard anesthetic in the surgical clinic. The discomfort of ether anesthesia when properly given by the open drop method by an expert can usually be practically eliminated. In the few cases in which the repugnance to ether is great, the sequence of gas-ether can be employed.

The closed method of giving ether is not so satisfactory or so safe as the open drop method. Complicated apparatus to control the percentage of ether and to warm ether possess no advantages over the simple drop method, and should be discarded. The giving of ether by the drop method is an art which must be acquired under the instruction of an expert.

NITROUS OXID GAS

1. Safety: Gas for short anesthesias, such as pulling teeth, opening abscesses, etc., is the safest anesthetic known. In prolonged anesthesias, a half hour or more, gas is now known to be more dangerous than ether. I refer now to the use of gas and ether in the hands of experts. In nonexpert hands, gas in prolonged anesthesias is much more dangerous than ether.

2. Comfort: Gas is the most agreeable inhalation anesthesia.

3. Gas is not an efficient anesthetic, such as chloroform or ether. Complete anesthesia and complete relaxation for prolonged periods are difficult to maintain, and are not possible in a considerable percentage of cases.

4. Control: Gas can at once be stopped at danger signals, and the agent already in the system is rapidly eliminated more rapidly than any other agent.

5. Simplicity: The apparatus for giving gas is not very complicated, more so, however, than that used in giving ether and chloroform. It is not so widely adaptable as ether. The apparatus is heavy and cumbersome, and somewhat difficult to transport. This objection can usually be overcome.

6. After-effects on blood tissues and viscera, practically negative.

7. Vomiting occurs in but a small percentage of cases.

8. It has little or no influence on immunity.

Conclusions.—Gas should be one of the general anesthetics employed in the surgical clinic. Its place should be for short anesthesias in which unconsciousness is desired and local anesthesia is not applicable—in reducing fractures and dislocations, opening abscesses, and in some more prolonged operations in which for special reasons gas becomes safer than ether, such as operations on the urinary organs with kidney insufficiency. A surgical clinic which does not frequently employ gas anesthesia is, from the standpoint of anesthetics, a poorly conducted clinic.

SCOPOLAMIN AND MORPHIN AS AN ANESTHETIC

1. Safety: A very dangerous anesthetic, so dangerous that it has now been generally discarded by general surgeons, and is retained only by a few enthusiastic obstetricians, the Freiburg school, and has been exploited as the "twilight sleep." The exploitation has been not only in medical journals but also in the lay press. A very thorough research on scopolamin and morphin has recently been completed by the obstetric staff of the Michael Reese Hospital in Chicago and reported by Baer.[1] This investigation shows that scopolamin and morphin should be rejected absolutely and finally as too dangerous, not efficient and as complicating the process and as threatening the asepsis, in short, the same conclusion that was arrived at by general surgeons some time ago. After scopolamin and morphin had caused a good many deaths, scopolamin and pantopon was substituted, and for a time it was claimed that this combination eliminated the risks; very soon, however, fatalities began to be rapidly reported. Then scopolamin and narcophin were suggested as a safe combination. This has not been employed as yet in a large enough series to warrant final conclusions, but deaths are already being reported, and there is no strong reason to hope that this combination is safer than its predecessors.

2. Comfort: No discomfort beyond the giving of the hypodermic injection.

3. Efficiency: Not efficient. It must be followed by a general anesthetic in a large proportion of cases.

4. Control: After once injected, it is beyond the control of the surgeon, and if a dose has been given which is toxic to that particular patient, little can be done to eliminate it.

5. It is simple and could be generally adopted.

6. After-effects on blood tissues and viscera are slight.

7. Complications: Delirium sometimes of serious character is not uncommon. Patients are frequently so dopey and out of their heads that they cannot cooperate with the surgeon or obstetrician.

8. Reduces immunity to pus microbe organisms.

---

[1] Baer, J. L.: Scopolamin-Morphin Treatment in Labor: A Critical Analysis of Sixty Cases, The Journal A. M. A., May 22, 1915, p. 1723. Baer says that the excessive thirst, headaches which are so distressing, the difficult control of patients, the risks of infection from soiling; the blurred vision, the ghastly deliriums constitute so severe an arraignment that "we feel compelled to condemn it."

SCOPOLAMIN AND MORPHIN PRELIMINARY TO ANESTHESIA

As a general anesthetic, scopolamin and morphin are to be absolutely and finally rejected both from general and obstetric practice. After it was generally agreed that scopolamin and morphin were too dangerous for use as an anesthetic, an extended trial of routine small doses of scopolamin and morphin preceding the general anesthetic were made, especially in Germany. The sequence has been responsible for many deaths. The evidence from the literature shows beyond question that even in small doses ¼ grain of morphin and 1/150 grain of scopolamin before chloroform, ether or gas adds distinctly to the risks of the patient. It complicates the giving of the general anesthetic. It masks danger signals. It adds to the percentage of vomiting and inability to void urine. It carries with it no advantage and many disadvantages and should be rejected. It is not a good thing, it is not a kindness to a patient to bring him to the anesthetizing room dopey and flighty. For some time after we had finally rejected scopolamin and morphin before a general anesthetic, we continued to employ it before using local anesthesia. We have now discontinued it even before local anesthesia, and find our results much more satisfactory and the local anesthesia quite as complete. In using local anesthesia, one must have the cooperation of the patient, and this one can have better with the patient in normal condition than when he is dopey. We have been pleased to find also that the occasional vomiting which occurred after our local anesthesias has practically ceased since discontinuing scopolamin and morphin, and that in our hernia operations the inability to void and the necessity to use a catheter does not occur. Preceding either the general or the local anesthesia, morphin and scopolamin should be rejected.

It is, of course, frequently necessary to use morphin on account of pain in surgical cases which later require operation under anesthetics, and where the indications are clear, morphin should not be withheld because the patient is to be given an anesthetic. The anesthetist should be informed of the fact that the patient has had morphin.

SPINAL ANESTHESIA

1. Safety: Very dangerous; more so than chloroform. Nine deaths occurred in the first 1,000 cases, and although it is difficult to give absolute statistics, there is probably more than one death in 500 cases.

2. Comfort: Not a comfortable thing, especially to an intelligent man who realizes what is being done. Few medical men with their knowledge of anatomy would choose spinal anesthesia in their own case.

3. Efficiency: The least efficient of the anesthetics except scopolamin and morphin. Necessary to supplement it with other means in from 5 to 10 per cent. of cases.

4. Control: When once injected, the agent is beyond control, and if the dose is a toxic one, the surgeon is helpless.

5. Simplicity: The method is not simple; it requires special technic and could not be generally adopted.

6. After-effects on blood tissue and viscera: These are largely expanded on the cord, and appear as cord injuries—the so-called aseptic meningitis.

7. Complications as above, and especially persistent and severe headaches lasting for days and weeks.

8. It has no effect on immunity.

That anesthesia can be produced by injecting cocain and its substitutes into the cerebrospinal fluid of the cord is an interesting fact. The method, however, has no place in surgical practice. It is too dangerous to warrant its employment, and for every surgical condition requiring an anesthetic, we have safer and more efficient methods at our disposal.

BLOCKING

By blocking I mean the attempt to anesthetize the field of operation by infiltrating the nerve supply of the part proximal to the site of operation, as blocking the gasserian ganglion, the brachial plexus, the great sciatic and anterior crural, the internal pudic, etc.

1. Safety: The method with good technic is fairly safe, except for such accidents as serious lesions from attempting to block the gasserian ganglion with resulting intracranial injury, injury to the vessels in blocking the brachial plexus, and more or less persistent paresis or paralysis of the nerve attacked from the direct trauma.

2. It is not a comfortable method. I have seen patients tortured in the attempt to block the gasserian ganglion, the brachial plexus and the internal pudic. The fact that the blocking of the nerve is often itself a surgical procedure is an objection to the method.

3. Efficiency: It is not always successful in producing anesthesia. Usually from fifteen to twenty minutes are required to produce full anesthesia, and in a considerable percentage of cases it is necessary to supplement it with other forms of either general or local anesthesia.

4. When once injected, the agent is beyond control; but inasmuch as the dose employed is or should be never toxic, this is not a serious objection.

5. Simplicity: The method is not simple; it requires often special training and technic, as in gasserian ganglion, brachial plexus, etc. It could not be generally adopted.

6. After-effects on blood tissues and viscera, nil.

7. Complications, vomiting, etc.: The method is free from them.

8. Effects on immunity, nil.

Blocking has but a limited field. Blocking of the gasserian ganglion, brachial plexus, etc., should be rejected. These are in themselves important surgical procedures, and cannot compete at all with the simpler and safer methods which we have at our disposal. In dental surgery the blocking of the inferior dental and branches of the superior dental nerves has a very useful field. As a rule, nerve blocking should be limited to the blocking of nerves which appear in a dissection made under local infiltration anesthesia, as blocking the ileo-inguinal nerve in a hernia operation done under local anesthesia.

LOCAL INFILTRATION ANESTHESIA

We have in infiltration anesthesia since the introduction of novocain and epinephrin a most important addition to our anesthetic agents.

1. Safety: Very safe when proper agents are employed and the technic is aseptic. Novocain in diluted doses of from 0.25 to 0.5 per cent. in normal salt with the addition of a proper amount of epinephrin seems to be very safe. From 6 to 8 ounces or even

more of this solution can be safely employed. In using small amounts of the solution, say, 1 or 2 ounces, 1 drop of 1:1,000 epinephrin should be added to each 200 drops of the 0.5 per cent. novocain in normal salt solution; in using larger amounts, from 6 to 8 ounces, not more than 20 drops of epinephrin should be used. I can find no report of a fatality from 0.25 or 0.5 per cent. of novocain. The addition of the epinephrin is most important. It produces a local anemia which prevents rapid absorption, and therefore makes the effect both safer and more prolonged. The epinephrin also reduces the bleeding to surprisingly small proportions.

A very definite warning should be given in regard to the use of epinephrin in too great concentration. Epinephrin in what is apparently a very weak solution is capable of producing necrosis of the tissues. I have seen this occur with the use of the tablets that are so frequently employed containing both novocain and epinephrin. It is not safe to use the tablets as ordinarily put up in any extensive operation, and these tablets should be very generally discarded and a definite warning sounded against them. I have seen no necrosis when the epinephrin has been 1:100,000, that is 1 drop to 100 drops of the novocain solution. I believe on the whole, however, that a safer rule would be 1:200,000, that would be 1 drop to each 200 drops of the novocain solution. This would be 10 drops in 4 ounces or 20 drops in 8 ounces, which might be regarded as the maximum amount to employ.

2. Comfort: If the technic is good, the anesthesia carries not more discomfort than the use of a hypodermic injection of morphin. In all cases one should inject first with a fine hypodermic needle 20 minims of the solution before using the larger needle and syringe. I tell a patient on whom I am doing an extensive lip carcinoma operation that I will promise him that he will have no more discomfort than from having a tooth filled.

3. Efficiency: With the large amounts of solution which can now be safely used, we can absolutely anesthetize the tissue infiltrated, and the anesthesia comes on at once and persists for from thirty to forty-five minutes.

4. Control: The agent after once being injected is no longer under complete control. Some control is retained, as operating on an extremity a rubber bandage is placed above the injection and free incisions would enable one to prevent rapid absorption and remove part of the fluid. I have, however, never seen any toxic symptoms or any necessity to resort to such methods.

5. Simplicity: The method is very simple and can be generally adopted.

6. After-effects on blood tissue and viscera, nil.

7. Complications, vomiting, etc.: Since we discontinued the scopolamin and morphin before our local operations, vomiting has practically disappeared. I have to report one incident which occurred in my series of cases. A week after operation for a benign breast tumor, a young girl had a thrombus of the axillary vein on the side opposite to operation. This cleared up in a few days, was painless and may or may not have been due to the local anesthesia.

8. Immunity not influenced.

Conclusions.—I believe that in local anesthesia with novocain and epinephrin we have a very safe and satisfactory method which should be employed in a large group of cases. Wilms is using it in a majority of his operations in the Heidelberg clinic. I am not prepared to go that far. I do not believe that the range of local anesthesia should be stretched too far. I am using it in about 30 per cent. of my cases.

INTRAVENOUS ANESTHESIA WITH ETHER

1. Safety: Both clinical and laboratory work shows that it is a dangerous method. Clairmont and Denk, after careful experiments on dogs, have concluded that it is too dangerous to employ in clinical work. Kuttner has two cases of lung embolism in twenty-three cases.

2. It is an agreeable anesthetic, as it does away with the disagreeable odor and irritation of inhalation of ether.

3. It is efficient, but the border line between anesthesia and a toxic dose is too narrow.

4. When once injected into the circulation, it is beyond immediate control.

5. The apparatus and technic are complicated and require special watchfulness. It could not be generally adopted.

6. After-effects are much the same as in the case of ether inhalation.

7. Complications are the same as with ether inhalation.

8. Effect on immunity is the same as with ether inhalation.

Conclusions.—Too dangerous, too complicated, no special advantages, should be rejected.

LOCAL INTRAVENOUS ANESTHESIA WITH COCAIN AND SUBSTITUTE FOR COCAIN

This was introduced by Bier and is an interesting piece of experimental work. It is a complicated method, however, requiring usually the exposure of a vein, and the distress of two tight rubber bandages above and below. It has no special advantages and should not be adopted as a practical method.

INTRARECTAL ANESTHESIA

This is an old method introduced as early as 1847 and revived from time to time.

1. Safety: It is not a safe anesthetic.

2. Comfort: It is not a comfortable method of taking ether.

3. Efficiency: It is not very efficient.

4. Control: Much the same as with intravenous anesthesia.

5. Simplicity: The method is complicated and cannot be generally adopted.

6. After-effects on blood and tissue same as inhalation anesthesia.

7. Complications: Distention of bowels, very severe local irritation of colon with colicky pains and bloody diarrhea often fatal.

8. Effect on immunity same as ether inhalation.

Conclusion.—Rectal anesthesia should be rejected.

INTRATRACHEAL ANESTHESIA

This interesting method, introduced by Meltzer and Auer, has not as yet been used in a very large series of cases.

1. Safety: Robinson collected 1,400 cases with seven deaths, one from lung rupture and one from emphysema.

2. Comfort: The same as drop ether which precedes the intubation.

3. Efficiency: It is an efficient method.

4. Control: The same as with drop ether.

5. Simplicity: It requires a complicated apparatus. It requires first anesthesia by drop ether and then a change to intubation. It could not be generally adopted.

6. After-effects same as drop ether.

7. Complications same as drop ether.

8. Effect on immunity same as drop ether.

Conclusions.—The method is dangerous. It is complicated and it possesses advantages in very few cases. When it was introduced it was welcomed as a simple method which had all the advantages of the complicated differential pressure methods which had been experimented with in thoracic surgery. As a matter of fact, both the complicated differential pressure and the intratracheal methods have practically been largely eliminated as a result of further investigations in thoracic surgery, which have demonstrated the fact that most of the operable cases in thoracic surgery can be done either under local anesthesia or drop ether or gas and oxygen; that the necessity of preventing collapse of the lung when but one pleural cavity is opened was theoretical and not real, and lastly, by the fact that the extensive work in which both pleural cavities are involved and such extensive work as attacking the thoracic part of the esophagus can not as yet be accepted as warrantable surgical procedures; furthermore, the introduction of the simpler method of intrapharyngeal anesthesia has eliminated the intratracheal method from the field of head surgery, in which for a time it seemed to have a place. On the whole, therefore, intratracheal anesthesia has little place in practical surgery.

INTRAPHARYNGEAL ANESTHESIA

This is an old method introduced years ago and reintroduced from time to time with changes in apparatus. Souchon developed a simple apparatus. A catheter was introduced through the nose or mouth into the pharynx, and with a hand bulb ether vapor was introduced. Potts, one of my assistants, invented a simple foot bellows to drive the ether vapor. Dr. Isabella Herb has made an apparatus in which the ether vapor is forced by a small air pump driven by an electric motor, taking its power from the ordinary electric light plug. The special advantage is that in mouth and jaw work after the patient has been anesthetized by drop ether, the mask can be removed, the catheter introduced into the pharynx through the nose or mouth and anesthesia continued without interfering with the operative field.

1. Safety: It is about as safe as drop ether.

2. Comfort: The same as drop ether, which it succeeds.

3. Efficiency: Not quite as efficient as drop ether but nearly so.

4. Control: Same as with drop ether.

5. Simplicity: It can be operated with a hand bellows, but better by an electric pump, if this is kept up in perfect working shape. It can be fairly generally adopted for use in mouth and jaw work.

6, 7 and 8. After-effects, complications and effect on immunity: Same as with drop ether.

MIXTURES AND SEQUENCES

There has been somewhat of a tendency, especially on the part of some professional anesthetists, to introduce in their work special mixtures and sequences, and complicated apparatus. I believe that, on the whole, anesthetic mixtures like the old shotgun prescriptions of the past should be avoided, and the patient's life should not be jeopardized by the administration of two or more powerful poisonous agents at the same time, one of which might intensify the action of the other or mask the ordinary danger signals. The sequences which I think should be accepted not as a routine but for special cases are the sequence of gas and ether, and local infiltrations supplemented with short gas anesthesia during some painful manipulation. The complicated apparatus to measure the percentage of ether and to warm ether possesses no advantages and should be relegated to the scrap heap. My assistants, B. F. Davis and F. B. McCarthy, who have gone into this matter fully and will shortly report on their work, summarize their results as follows:

WARMED ETHER IN ANESTHESIA

The amount of heat required to warm ordinary ether vapor as used in anesthesia by the open or closed methods by intrapharyngeal or intratracheal insufflation to body temperature is so small as to be a negligible factor in lowering body temperature and inducing shock in anesthetized patients. During an hour's anesthesia with the coldest ether vapor, one is likely to obtain, say, 8.5 C.; the heat used in warming the anesthetic is equal to that lost in climbing up 75 feet of stairs, and this spread over the entire hour. No more mucus and saliva is secreted when anesthesia is induced and maintained with cold than with warm ether. So-called cold ether vapor does not appear to be more irritating to mucous membranes than warmed ether. The quantity of ether required to produce and maintain anesthesia does not appear to be materially influenced by warming ether. The warming of ether vapor, however administered, is accomplished in the mouth, pharynx and trachea, and the anesthetic reaches the alveoli at body temperature.

It has been shown that with percentage-measuring machines there is danger of continuing too long the high percentage vapor, that is, the anesthetist watches the dial of his machine and not the patient. A jar which will allow air to be passed over the ether, through the ether, carried over the ether without coming into contact with it at all, or any combination of the foregoing routes is easily constructed, cheap and satisfactory. The rate of administration of the anesthetic may be governed by the same guides as in the drop method.

There appears to be no reason for the adoption of any of the expensive and more or less complicated ether-warming or percentage measuring machines which are offered for sale.

ANOCIASSOCIATION

We are all familiar with the interesting work which Crile has been doing under his so-called anociassociation method. When I heard Crile present the subject I was greatly interested. When I saw his brilliant work in his operating room I was delighted with his technic and his admirable surgical methods in general. No one can find fault with Crile's general statement that "the prevention of shock in operations under inhalation anesthesia is, as it seems to me, most effectively accomplished by the conservation of the energy of the patient, by the prevention of the loss of heat, loss of blood, the exclusion of psychic influences, a minimum trauma of sensitive tissue, by a featheredge dissection," etc. But when he adds that he can wholly prevent shock by sequestering the brain from the field of operation by blocking the nerves with novocain, we cannot accept either his assertion or the experimental work on which this is based.

To begin with, none of us know what shock is. Physiologists who have devoted much time and study to the subject are not agreed among themselves as to just what shock is, and most of them admit that they do not know. Many of them have repeated Crile's experimental work, and practically none of them accept his theory or his results.

As examples I submit the following conclusion of experimenters who have investigated this subject:

> JANEWAY and EWING:[2] If trauma to the sensory nerves is a factor in production of shock in an unconscious animal, it is wholly subsidiary to other factors, and it is questionable whether it was apparent in our experiments even when these other factors had rendered the nerve centers more vulnerable by toxic influences, as ether, or by a fall in blood pressure.
>
> PORTER and QUINBY:[3] The symptoms of shock are a clinical entity about which there can be little dispute. Shock, on the contrary, is a pathological state, the data of which are at present hypothetical. The hypothesis which constitutes the hitherto generally accepted definition of shock declares that the vasomotor cells are depressed, exhausted and inhibited by excessive stimulation of afferent nerves; the fall in blood pressure and the accompanying symptoms are the result of this depression. The experiments cited in this paper demonstrate that the vasomotor cells are not thus depressed or inhibited, and experiments published in the last number of this journal show that excessive stimulation of afferent nerves does not materially lessen the blood pressure. The present hypothetical basis of shock is thus removed.
>
> SEELIG and LYON:[4] In conclusion, it is important again to emphasize the fact that the experimental work detailed in this paper is in no sense of the word to be taken as an explanation of the causative factor or factors of shock. Just as Porter claims to show explicitly that in shock the vasomotor center is not exhausted, and therefore implicitly that the peripheral vessels are not paralyzed, so we try to show explicitly that the peripheral vessels are contracted and implicitly that not all the vasomotor centers can be exhausted. The complexity of the vasomotor apparatus with its multiplicity of centers and the seemingly independent action of many of these centers, render it impossible to frame a satisfactory theory based on our results. This much may be said with assurance: If the work herein detailed stands the test of confirmation, then the doctrine that shock is due to vasomotor exhaustion must be revised.
>
> MANN:[5] It is impossible to reduce the anesthetized animal to a state of shock by any degree of sensory stimulation, provided all hemorrhage is prevented and its abdomen is not opened.

After analyzing Crile's work and the work of competent physiologists, I have been forced to the conclusion that there is no scientific basis for Crile's statement that he can wholly prevent shock by sequestering the brain from the field of operation by blocking the nerves with novocain. Crile's excellent surgical work is done not because of anociassociation but in spite of it.

The complicated sequence of scopolamin and morphin, gas, oxygen, ether, novocain and quinin and urea hydrochlorid is a method open to many objections. The scopolamin and morphin, as I have attempted to show in this analysis, add distinctly to the risks of the patient and should be omitted. The gas-oxygen plus ether, if used alone, is an acceptable anesthetic sequence, but not so safe as a routine as drop ether and gas and oxygen used alone in properly selected cases. Novocain used alone in infiltration anesthesia is of great value and has a wide field of usefulness. Used in this sequence it has little value, certainly none in preventing shock. Quinin and urea hydrochlorid has no value in this sequence, and used alone as an anesthetic cannot compete with novocain and epinephrin. I believe, therefore, that we must reject both the theory and the practice of anociassociation.

CONCLUSIONS

The final results of my analysis of the anesthetic problem are as follows:

1. Drop ether should be today chosen as the standard general anesthetic when a prolonged anesthetic is desired with relaxation and unconsciousness.
2. Intrapharyngeal ether should be chosen in mouth and jaw cases when it is desirable to remove the anesthetist and the anesthetic apparatus out of the operative field.
3. Gas should be chosen in short anesthesias in which unconsciousness is desired, and in special cases, such as kidney insufficiency.
4. Local infiltration anesthesia should be chosen when the surgeon has the full cooperation of the patient and when the field of operation can be completely infiltrated and anesthetized by a safe amount of novocain and epinephrin.

These four simple and safe methods can be made to cover all surgical cases. This places anesthesia on a very unpretentious, simple basis, but here as in most fields of surgery, we finally learn that simplicity is near to truth.

122 South Michigan Avenue.

The Control of Communicable Diseases.—The monthly *Bulletin* of the State Department of Health of New York makes this subject the chief feature of the September issue. It points out that the loss of life from typhoid fever, diphtheria and scarlet fever remains too high. These three infections, together with measles and whooping cough, were responsible for the deaths of over 5,000 people, mostly young children, in New York State last year. This issue of the *Health News* contains an account of four outbreaks of communicable disease. Septic sore throat in Westchester County was spread by contact and secondarily to a slight extent by milk; scarlet fever in Dutchess County was spread primarily by milk and secondarily by contact; diphtheria in Rockland County, by milk, and in Westchester County, by contact. Therefore, the remedies which would guard against such outbreaks are simple—pasteurization of milk and isolation of early cases of disease. These four epidemics included nearly 1,400 cases of disease. From this experience the following lesson is emphasized: 1. Unpasteurized milk is unsafe to consume. 2. Local health departments can prevent outbreaks of this kind by requiring the pasteurization of milk before delivery to consumers. 3. In the presence of scarlet fever all cases of sore throat should be treated as septic sore throat, which is reportable to the local health department.

PROJECTILE WOUNDS OF THE HEAD

EXPERIENCES DURING RECENT SERVICE IN AUSTRIA, WITH PARTICULAR REFERENCE TO WOUNDS OF THE EYES *

LLOYD MILLS, M.D.
LOS ANGELES

The material for this paper is drawn from over 300 cases in my own wards of the Vienna General Hospital, where, after serving for four months as voluntary assistant in the Fuchs clinic, I was given charge of two wards of this service, these wards being devoted to the care of the wounded and especially of eye and head injuries. I was further able to observe and to assist in the surgery of over 800 other wounded in the associated wards of Professor Büdinger's service, among whom were a number of face and head cases. From army surgeons among these patients, I was also fortunate in gleaning much interesting matter relative to the rapidly fatal wounds seen on the firing line.

In the first month of the war comparatively few head injuries were received, because the fighting was in the open; but with intrenchment operations on a large scale, the number rose rapidly.

Because of the position of the men in the trenches, wounds of the head are probably the most frequent of all injuries, their frequency being masked in the hospital lists of wounded by the fact that fully 95 per cent. of all short-range wounds of the head are immediately fatal because of the literal ruin which the modern sharp-nosed bullet makes of the cranium and its contents.

Facial wounds are very common and may be serious if the eyes are involved, or if the mastication is impaired through damage to the jaws or their articulations. The central part of the face, however, may be traversed in all directions by undeformed bullets, with the tissue destruction practically limited to the bullet's path because of the spongy nature of the bone, and this, apparently, without regard to the velocity of the missile. Infection of the sinuses is the rule when they are perforated, but when the splinters of bone are removed and free drainage provided, healing takes place with unusual rapidity. The lower jaw frequently suffers extensive comminution because of its compact structure, and the fragments of bone and the dislodged teeth often act as infecting secondary missiles or tear away considerable portions of the lower face.

Some idea of the terrific impact of the modern spitzer bullet may be gained, when it is understood that the 10-gram German bullet has a muzzle velocity of about 2,900 second-feet, and revolves on its long axis, its boring and chief pathologic motion, about 2,500 times per second. In terms of energy, this means that at 100 yards, the bullet has a working force capable of raising a weight of over three quarters of a ton to a height of one foot, and at 300 yards a half-ton would be raised an equal distance, while at 500 yards the force drops to about 600 foot-pounds. Consequently, it becomes obvious why so few of the short-range bullet wounds of the cranium figure in the lists of the base and reserve hospitals.

Reconstruction of skulls shattered by the modern pointed bullet shows that the undeformed bullet passes completely through the skull and emerges before the collapse of the cranium occurs. Until very recently this collapse was supposed to be due to a so-called "explosive action" of the missile, but careful reconstructions show that radial and circular fissures arise from both the wound of entrance and that of exit and so interlace that finally the cranial dome becomes converted into a myriad of fragments. These fragments tumble into the general ruin and are dissipated far and wide through the transmission of the energy of the bullet to the brain substance, which spreads and storms out through every fissure. When the missile is deformed, and the modern bullet seems to have the property of flowing out of shape with uncommon ease, the effect on the head is the same as on the rest of the body, tremendous laceration and loss of tissue.

At ranges above 500 yards, the lessening in the energic activity of the bullet is rapid, so that at 1,800 yards, which is somewhat less than half the range of the German arm, only two slightly splintered wounds may be made in the skull. At such a range, if the skull and brain have merely been guttered, the patient has some chance for his life, and this seems to be especially true when a lateral shot has grooved the surface or tip of the frontal convolution, a part of the brain comparatively tolerant to physical insult.

The importance of these frontal wounds to the eye surgeon lies in the comparative frequency of the accompanying fracture of the orbital plate, a fracture which was long offered as a typical example of the "contrecoup," but which we now know to be part of the system of radial fissures produced by the splitting lateral, rotary action of the bullet on bone, or of the system of circular fissures, which are chiefly bending and bursting fissures, produced where the lines of transmitted energy or stress meet and oppose. Probably careful examination would also disclose quantitative or qualitative olfactory changes in these cases, as it is not easy to conceive of the weak cribriform plate of the ethmoid escaping uninjured. The results of such fractures of the orbital plate vary from slight to severe degrees of bleeding into the orbital fat, the upper lid and the conjunctiva, with more or less *protrusio bulbi*, to cases as grave as the following, which is offered as an addition to the causes of pulsating exophthalmos:

Case 1.—F. W. was admitted, Oct. 28, 1914, with an oblique bullet wound of the right frontal region, which had ruined the right frontal boss, had opened the skull and the frontal sinus, had guttered the right frontal convolution and had produced three sagittal fissures in the right orbital vault, fissures radiating from the entrance wound. The margins of the wound were black from necrosis, and its depths were filled with pulsating, stinking fluid, and rotting cerebrum. The symptoms were severe headache and prostration and frequent vomiting. The lids of the right eye were pushed forward and everted by a markedly protruding and pulsating globe, which squeezed the conjunctiva forward in great, red chemotic folds. The sclera was deeply injected and the cornea was dulled by a beginning lagophthalmic ulcer. The anterior chamber, strangely enough, was of normal depth. The iris was discolored a dirty yellowish green, and the pupil was dilated and quite immobile. There was no red fundus reflex and the eye was amaurotic. The diagnosis lay between a pulsating exophthalmos, due to traumatic arteriovenous aneurysm from the laceration of the retrobulbar vessels by bone splinters, and a great orbital hematoma from the same cause. The wound was enlarged, cleansed of loose brain and bone fragments, and two long, loose anteroposterior fragments of the orbital plate were removed. Before this was completed, it had become evident that no extensive hematoma and no aneurysmal varix existed here. Instead, the lacerated frontal brain, with much accompanying serum and cerebral fluid, had poured through the widely spread breaches in the orbital plate, had driven the eye forward and had transmitted the cerebral impulse to the protruded ball. The final diagnosis was "pulsating exophthalmos from cerebral hernia into the orbit, after extensive fracture of the orbital plate." The patient died shortly after of a virulent dysentery of the Flexner type.

---

* Read before the Section on Ophthalmology at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

One of my surgeon-patients told me that at the front it was by no means uncommon to observe distinct pulsating exophthalmos as an antemortem sign among the frequent cases of side-to-side perforation of the lower temporal region.

Of course every known variety of eye injury occurring in civil life has its duplicate in battle injuries. In a number of such cases, some types of injury, however, are likely to stand out by reason of their frequency, and this has been the basis of my rough grouping of the cases which fell to my care or came under my observation.

1. The most frequent type of bullet wound as well as the most disfiguring wound of the orbital region, was that in which the antero-external wall of the orbit was cleanly shot away, the bulb always being ruptured. The exposure resulting was so nearly identical with that given by the Krönlein operation that I called these cases "Krönlein shots." In our series the right eye was injured in this way about twice as frequently as the left.

2. In many cases in which bullets struck or perforated the orbital cone, without touching the globe, the globe was shattered by indirect violence; or if this was not great enough to produce a rupture, lesser expressions of force appeared as iridodialyses, dislocations of the lens or rupture of any of the tunics of the eye, alone or in any combination. Reports of four different cases of this type follow:

Case 2.—Lieut. F. was shot from the rear while leading a charge up a hillside during the first Serbian campaign. The bullet entered at about the middle of the scapular origin of the right trapezius, continued obliquely across the right neck to the lower jaw, comminuting part of its alveolar and all of its coronoid process, perforated the superior maxilla and malar bones and emerged from the external angular process of the right frontal bone. The orbit was not entered, yet the lower lid was torn away from the inner canthus, its conjunctiva lacerated horizontally in three places, and the cornea, iris and ciliary body were ruptured horizontally at about 190 degrees. Enucleation and a plastic operation on the lid were required. This case was of further interest in that the trismus, which followed the shattering of the coronoid process, simulated tetanus and rendered feeding so difficult that the question of ultimate starvation actually arose. This was overcome by gradual, forcible opening of the mouth and by the later removal of necrotic jaw-bone through the mouth.

Case 3.—A private was shot in the right cheek while sighting his rifle. The bullet entered just below the center of the attachment of lower lid to orbit, perforated the superior maxilla, crossed the antrum, leaving several large fragments of bone in its wake, and finally emerged from the mouth through the palate, which it fissured freely in the coronal plane. The orbit was not entered. The right eyelids were edematous, the conjunctivae injected and considerable ciliary injection was present. The cornea was normal and the anterior chamber of normal depth but with a slight hyphemia. The iris was clearly marked, but was discolored to a greenish blue.

No fundus examination was possible on admission because of hemophthalmos, but this lifted in about two weeks, revealing a ragged tear squarely through the macula and curving downward and inward for about 6 mm. The retina in this situation showed the characteristic changes of a retinitis proliferans.

The vision at the time of discharge was 6/3 with the left eye and finger counting at 2 cm. with the right. In this case, as in practically all cases in which bullets open the accessory sinuses, empyema resulted, but healed in about twenty days after the fragments of bone were removed through the canine fossa, and free drainage established.

Case 4.—The patient was struck squarely over the left frontomalar suture by a spent bullet from a machine gun. The missile had so little energy left that not only could it not penetrate the hard bone, but also it dropped back out of the wound. On admission, the iris was found to be torn radially down to its root at about axis 45, the lens was luxated downward and the black sickle of the ciliary body could be seen running from axis 20 nearly to axis 50. In this situation especially there was marked iridodonesis. The lens was gray-white and swollen forward into the pupil. Repeated Roentgen examinations detected no foreign body in eye or orbit, so the diagnosis of capsular rupture by indirect violence was made. Atropin was given, but the tension rose to the point where a linear extraction was made necessary.

Case 5.—J. K., sergeant, aged 28, and a lawyer in private life, was shot in Russia, October 23, and admitted, October 29. The left lower orbital margin was shot away from left to right, producing a large coloboma of the lower lid. The ball passed through the inner canthus and the nose and emerged 1 cm. below the inner canthus of the right eye. Neither eye suffered direct violence from the missile or from bone fragments. The attachments of the internal and inferior muscles of the left eye were torn away, its sclera was ruptured in several places in the lower inner quadrant, the cornea was wrinkled and the bulb collapsed. The shallow anterior chamber held blood.

The principal changes in the right eye consisted in a considerable hemophthalmos and a 6-mm. long circular rupture of the sclera, lying midway between limbus and fornix in the upper inner quadrant. Through this rupture the vitreous had flowed, to lift up the conjunctival covering in the form of a transparent semiovoid, through which came the dark shimmer of the uvea. The iris was pulled so strongly outward and upward that less than its lower half was visible. By November 18, the right eye was partly freed of blood and could perceive light at 3 meters. Temporal projection was false, but nasal projection was accurate. The conjunctivitis of both eyes, which had resulted from the large openings into the nose, was cleared up by this time and permitted the enucleation of the left eye, with a suture of the upper lid to the margin of the great coloboma of the lower lid, for the best cosmetic result. At the same sitting, three deep mattress sutures of silk closed the scleral rupture.

One of the most interesting facts which these cases of indirect violence have shown, and a fact which is of the greatest importance in any consideration of the mechanism of the production of bullet wounds, is that the injury to the bulb is seldom, if ever, in a direct line with the line of incidence of the blow, but is usually nearly at right angles to this line. This must be accepted as the effect of the rotary, boring motion of the bullet, produced by the rifling of the barrel and which, as demonstrated here, in shots of the brain and by its action on bone and on soft organs like the liver, is by far the most pathologic motion of the bullet. That this rotation of about 2,500 times per second, at the rifle muzzle, could have gone so long unconsidered as the source of most of the lateral trauma along the bullet path, seems strange, in view of the radial splits and fissures which stream out at, or nearly at right angles to the course of every bullet, in soft viscera, as well as in bone.

3. Probably shrapnel and other shell explosions are the most common cause of unilateral blindness, and

lead most frequently to enucleation, from direct perforation of and lodgment in the bulb, with or without infection, or from the frequency with which malignant serpent ulcers follow the not uncommon corneal abrasion. Curiously enough, small shrapnel fragments seem to be less often the corneal abraders than the particles of dirt which spurt to all sides in clouds when the shell explodes on or just above the ground. The high explosives with which shells are charged may break them into two or three thousand fragments, of sizes which vary from the great, irregular masses of metal which have all the terrible lacerating effect of solid shot, to the finest, dustlike particles whose presence in structures like the eye is often demonstrable only after repeated roentgenograms.

The smaller shrapnel fragments produce all the types of perforating injuries seen in civil life, traumatic cataract, iris prolapse and hemophthalmos being perhaps most often observed. Panophthalmitis is not uncommon, as might have been anticipated from the high percentage of infection following shell and shrapnel injuries of other parts of the body. As I have reported in a previous article,[1] this percentage reached over 85 in our general series of shrapnel and other shell wounds.

Our common rule in these cases of perforating wounds produced by shell fragments was prompt enucleation where there had been material damage and when fragments of any size were lodged in the globe and were not easily accessible. Local anesthesia could not be employed here because of the unusual tenderness and the frequency of an accompanying low-grade orbital cellulitis and of unusual bulbar and conjunctival adhesions. No enucleation was deferred because of a mild orbital cellulitis, nor was any change made in the usual method of operating, yet in no case was there the least sign of meningeal extension of the orbital inflammation. When very small and dust-form fragments were the offenders, expectant measures were used if the vision was not diminishing and if the eye was not tender or had no noticeable amount of reaction. Of course, such patients were kept under close observation and, when discharged, were cautioned to report themselves at the slightest sign of intolerance to the foreign body. The results following the removal of shrapnel and other shell fragments were much more unsatisfactory than those following the removal of similar metallic fragments in civil life. This was probably due to the much greater length of time ensuing between injury and operation and to the greater frequency of infection.

4. Our cases of war psychoses, among which hysterical amaurosis is included, were all the result of a shell of some sort bursting unexpectedly in their neighborhood.

The following case is fairly typical:

Case 6.—L. R., aged 29, a sergeant-major and in private life a bookkeeper, stated that a shrapnel struck the ground in front of him and burst at the very moment of striking. For a moment he was unconscious and thereafter saw everything so clouded and so imperfectly that, in trying to obey orders, he led his men in the wrong direction and commanded them to fire in the direction of his own main body of troops. Seven days after the battle, the movements and external appearance of the eye were found to be normal. Both pupils reacted briskly and the fundi were normal. Vision was reduced to the perception of hand movements. With a +10 sphere the right eye could count fingers at 5 cm., and with a +8 sphere the left eye counted them at 3 cm. The fields of vision were shrunken to mere points. A nerve examination showed a right facial analgesia, but all other reflexes were normal. Treatment consisted of sweating and complete rest in bed for several weeks, together with the assurance of complete recovery. Later faradization and strychnin sulphate injections into the temporal regions aided in a very slow but constant improvement, which, in our belief, was retarded by the patient's unwillingness to face the prospect of a return to the front. Several of our patients who suffered from war psychoses declared that the air pressure produced by the explosion was the real causative factor in their conditions, as it had hurled them several meters high into the air, a seemingly obvious misstatement.

5. About a sixth of our eye cases were those in which the strain of hard campaigning on insufficient food, and with exposure to weather and to filth conditions, had produced the same ocular diseases or recrudescences which might be expected to follow similar strain or exposure in civil life. The most noticeable among these were recurrent cases of rheumatic iritis, keratitis eczematosa and parenchymatosa, chronic and acute conjunctivitis and serpent ulcer. One case of severe rheumatic iritis occurred in a Jewish private who had deserted and come to us after his regimental doctor had repeatedly refused him treatment on the ground that nothing was wrong with the eyes.

A rather frequent cause of corneal ulcer was from dirt thrown into the eyes in the strenuous digging of hurried intrenching or in the unexpected caving in of trench walls.

I am confident that one sequel of this war will be the extension of trachoma, which was being well limited in Austria and Germany, but which is now being freely introduced throughout both countries by the hordes of refugees from infected districts.

6. Another interesting group of cases was referred to us from all sides. These were cases in which the eye had been shattered at periods of from one to four weeks prior to admission. When the injury was not more than a week to ten days old, scleral and rarely corneal residues could be made out in the depths of the wound, but beyond that time the vigorous conjunctival growth almost invariably buried them beyond recognition, and an exploration was often necessary, when, as frequently happened, no history accompanied the patient.

In every case of this sort the residues were carefully removed as a prophylactic against later cystic or malignant growths, as well as for their possible influence on the sound eye. Without exception the conjunctiva was adherent in unusual situations, and the conjunctival sacs were so greatly shallowed that, even after free dissection of the unusual bands and adhesions, a good cosmetic result with regard to wearing artificial eyes was seldom obtained.

7. Several of the many irregular cases are worthy of record:

Case 7.—An infantry captain, who was wearing his pince nez into action, felt a sharp, stinging pain in his right eye, following the explosion of a shrapnel several meters in front of him. As his lenses were undamaged he supposed that flying dirt had hit his eye without injuring it. On testing the eye, however, he found that he could see nothing with it. Even then his regimental surgeon, who had made an external examination and had found no wound or obvious change, assured him that nothing was the matter, but his rank procured him attention, without the need of desertion, and he was referred to us about five days after the injury. No wound could be found in cornea, sclera or conjunctiva, but blood was present in the vitreous and prevented ophthalmoscopic examination. The roentgenogram revealed two fine shrapnel splinters in the posterior upper and inner quadrant of the vitreous, and as vision did not improve during the two weeks following and the eye became somewhat sensitive to pressure, I was obliged to enucleate. The main interest of this case is in the manner of injury. The only possible path for the shrapnel fragments to have taken without breaking the glass before the patient's eye was between bridge and lens, entering the tissues just at the inner canthus, passing behind the transitional fold in this situation and entering the sclera at or just behind the equator.

---

[1] Mills, Lloyd: Wounds Received in Battle, The Journal A. M. A., April 10, 1915, p. 1224.

Case 8.—A private was shot in the right lower lid. The shot was supposed to have been merely a gutter shot of the lid, although the reason for a vision of 6/18 was unexplained. No limitation of motion was observed that could not be accounted for by local reaction to trauma. About three weeks after the injury the lower lid became inflamed, and on reopening of the wound an undeformed bullet was found lying snugly in the soft tissue beneath the bulb, slightly in front of the equator, its axis in the coronal plane. Vision returned to 6/6 almost immediately after the removal of the foreign body.

Case 9.—A shell burst just behind a young color-sergeant, and his right occiput was perforated by some of the fragments. He was transferred to our service about two weeks after his injury because of an increasing ulcer of the left cornea. The roentgenograms showed three jagged metal fragments, about the size of beans, lodged in the nuclear region of the upper cranial nerves in and slightly to the left of the middle line of the body. The whole right side of the trunk was paralyzed, apparently from pressure on or destruction of the left pyramidal tract before its decussation. There was complete paralysis of all intrinsic and extrinsic muscles of the left eye, representing lesions of the nucleus of the third left cranial nerve, of the fourth right nucleus and of the nuclei of the sixth nerves. The right external rectus and the superior oblique were paralyzed, and the right pupil was dilated and reacted feebly and sluggishly to strong light. A deep and widely infiltrated ulcer of the left cornea had resulted from the ptosis and combined sensory paralysis.

The left side of the face was wholly paralyzed, the origin being a lesion of the seventh nuclei. This lesion was probably the initial cause of the corneal ulcer, for the left corneal reflex was lost. In such a case the distinction between neuroparalytic ulcer and lagophthalmic ulcer is rather fine. No accurate hearing tests were made, but hearing was greatly reduced in both ears. That the ninth nuclei were also involved was shown by difficulty in swallowing, thick speech and constant drooling. No attempt was made to remove the shell fragments, although such an attempt offered the only frail hope of betterment. The left eye atrophied after iridocyclitis.

8. The last prominent group of cases owes this prominence directly to the use of the modern sharp-pointed, high-powered projectile. These are the sad cases of bilateral blindness, due to destruction of, or vital injury to both bulbs, to both optic nerves, to the retrobulbar vessels, or to any combination of these injuries. While fragments of shells of all kinds are responsible for many of these cases, the modern bullet is the chief instrument in the production of these most terrible of battle-wounds. Victims of the short-range wounds of the regions involved, as has been shown, happily, rarely survive; but the penetration of the modern bullet, at ranges above 1,500 yards, is still so great that it can destroy the visual apparatus of both eyes and yet often allow the victim to live miserably on. Because of its far smaller power of penetration, the older arm at long range far more often led to lodgment of its coarser missile in the bone or brain, before both visual tracts were destroyed. If what I have witnessed in Austria and Germany is any criterion, then the frequency of this terrible injury should, alone, lead to the abandonment of the spitzer bullet, or at least to its modification.

Every clinic is furnishing its heavy quota of these pitiful cases, nearly all of them young, strong men and nearly all so overwhelmed by their terrible misfortune that they would and often do accept any means of suicide when the fact of their blindness finally becomes an assurance to them. When these brave men soberly and earnestly pray for death, it is a pity that any power, whose inhumanity is so wholly responsible for their grief and suffering, will not either make these men and their families quite independent for life, or else give this longed-for boon of euthanasia in slight return for all that has been sacrificed to the names of patriotism and of country.

1669 West Adams Street.

ABSTRACT OF DISCUSSION

Dr. Lloyd Mills, Los Angeles: In so far as I am aware, the production of a vacuum by a bullet has never been considered as a factor in the production of trauma. Until the experimental work of Victor Horsley on projectile wounds of the brain, the forward motion of the bullet was held to be its only pathologic one. When the eyeball is struck by the bullet, the principle of incompressibility of fluids comes into play and the globe is always completely shattered.

Dr. John A. Donovan, Butte, Mont.: In addition to the destructive action of the modern bullet, just explained, it has a suction or vacuum-creating action, which in my opinion explains one of its awful death dealing effects. On man this is hard to demonstrate, which accounts for its being so far overlooked, but on larger animals it is marked. I have repeatedly seen the stomach contents evacuated through a bullet exit hole out of all proportion to the size of the hole or any natural pressure effect; also long loops of intestine, apparently drawn through exit bullet holes. To my mind the suction evidence was most conclusive in shooting an elk. My bullet passed through the body, perforating intestines and stomach, broke a rib, was deflected, and broke the front shoulder. Between the ribs and skin, following its course, was fecal matter, completely filling a space about three-quarters inch in diameter, and over 10 inches long. My guide exclaimed in astonishment, "The elk has a gut going to its shoulder." This could occur only by a most powerful suction action, which is furthermore confirmed by the fact that a lung wound in a big animal with these bullets has almost no stopping effect. I refer to our own army 1906 sharp point 150 gr. bullet, turning once in 10 inches, and having a velocity of 2,700 feet per second. The enormous vacuum created can be more easily comprehended by stating that this initial velocity is practically 1,800 miles an hour.

Heart Block.—The prognosis and treatment in heart block depends largely on etiology. Where the block is due to overstimulation of the vagus nerve, such as is seen in digitalis poisoning, stopping the digitalis and paralyzing the vagus with atropin will usually bring about a return to normal. Where the block is complete, heretofore it was thought always to be due to some organic division of the conducting path. We now know that in some of these cases there is not a complete, permanent division of the bundle, but complete block may be due to more temporary causes, such as poisoning from infectious diseases or asphyxia. In this class of cases complete recovery sometimes occurs. Even in the cases of organic origin, after the symptoms of syncope have persisted for some time, a degree of toleration becomes established and circulation is carried on with the slow ventricular rate. Such patients, however, are never able to undertake any but the most restricted activities.—W. H. Lowman.

CHOLECYSTECTOMY AND CHOLECYSTIC TOXEMIA *

W. WAYNE BABCOCK, M.D.
Surgeon to the Samaritan Hospital
PHILADELPHIA

According to the mode of invasion, gallbladder infections may be divided into four types:

1. Portal infection, in which bacteria entering the portal circulation, chiefly from the alimentary tract, escape the bactericidal action of the liver and passing out with the bile, colonize in the gallbladder. This method, described years ago by Adami, has been considered as quite common and is supposed to explain the relationship between appendicitis, intestinal ulceration and other inflammations of the alimentary tract and gallbladder disease.

2. Ascending biliary infection, in which bacteria ascend from the ampulla of Vater through the common and cystic ducts and enter the gallbladder. This process is aided by the reversed mucous currents described by Bond, who showed that carmine particles introduced even as low as the rectum would after a time pass upward against the normal peristaltic current, and be discharged on the surface of the skin through a cholecystostomy opening. Although probably less frequent than other methods, ascending biliary infection occurs in certain inflammations and new growths involving the duodenum.

3. Hematogenous infection, in which bacteria circulating in the general blood stream invade the gallbladder. Rosenow has shown the specific manner in which certain streptococci circulating in the blood, attack the gallbladder or produce gastric ulcer, and his experiments suggest that many causes of cholecystitis formerly considered of a portal or ascending biliary type are in reality focal hematogenous infections. The well-recognized metapneumonic cholecystitis of young children apparently occurs in this way, as does the infection of the gallbladder in typhoid fever.

4. Contiguity infection, in which the gallbladder is involved by the spread of infection from adjacent organs, as when an adjacent abscess perforates, or malignant or benign ulcer of the stomach or duodenum invades the gallbladder. This is a relatively rare form of cholecystic infection.

Frequence: Infections of the gallbladder are exceedingly common. Next to appendicitis, cholecystitis is the most frequent of all the chronic intra-abdominal infections. In some classes of people, notably obese, middle-aged multiparas, it is more frequent than appendicitis. It is the second great cause of chronic indigestion. Inflammation of the gallbladder often develops during the first and second decades, but as the local symptoms are unobtrusive, the condition usually escapes recognition. After middle age, as the local symptoms become more predominant, the diagnosis of gallbladder disease is made. Thus we have been accustomed to consider it a disease of middle or advanced life.

Persistence: Infections of the gallbladder are exceedingly chronic. It has long been known that typhoid bacilli may continue to multiply for thirty or forty years in the gallbladder. It is now recognized that other bacteria likewise may have persistent growth. The bacteria are found in the center of the gallstone, in the bile, and in the mucosa lining the gallbladder wall. Bacteria found in the center of gallstones and within the depths of the mucosa usually represent more or less remote infections and may be associated with bile that is practically sterile. At present, although most of the patients operated on for gallbladder disease have reached the fourth or fifth decade of life, a careful study of the history usually indicates that these same patients acquired their infection in the second or third decade. As yet we have not learned to sterilize the chronically infected gallbladder and the patient once infected may be continuously infected until the gallbladder is removed, or until a violent necrotic form of inflammation destroys the lining of the mucosa and leaves the gallbladder a shrunken, functionless mass of fibroconnective tissue. The temporary relief that follows medical treatment, or a Carlsbad course, prompts the patient and physician to defer operation until advanced pathologic changes have occurred. After a simple drainage operation, the bile clears and the patient is relieved, but the deep infection in the gallbladder wall persists and the symptoms of chronic cholecystitis may later recur. If the symptoms are not of the obstructive type, the patient will usually tolerate them, although not infrequently more radical treatment is demanded.

Symptoms of cholecystitis: Apart from a small area near the neck the gallbladder has no sensory nerves, and distention or inflammation produces no symptoms unless the irritation spreads to adjacent sensitive structures. In operating under local anesthesia, we have repeatedly incised, sutured and crushed the wall of the inflamed gallbladder without pain. Only when traction or pressure affects the ducts, other sensitive organs, or especially the parietal peritoneum, does the patient complain. One should not, therefore, expect local symptoms in inflammations that are limited to the gallbladder proper.

Symptomatically, we would divide chronic cholecystitis into three stages:

First, a stage marked by more or less remote reflex and toxic symptoms and by the absence of local symptoms. This is the stage of cholecystic indigestion and toxemia and represents a period in which the gallbladder factor is usually unrecognized. It usually continues from fifteen to twenty years before the development of the second stage. In this first stage the mortality under operative treatment should be under 1 per cent.

Second, a stage characterized by the movement of calculi, or by recurrent attacks of acute inflammation. Stones cause paroxysms of pain usually by obstructing the outlet of the gallbladder. The attacks are violent, often follow indiscretions in diet, usually require an opiate, frequently occur at night and last but a few hours. To be differentiated are the acute recurrent attacks of cholecystitis in which no calculi are present. The latter are less violent, usually do not require an opiate, last several days instead of a few hours, and have an onset and termination less abrupt than the colic produced by stone. On exposure, these gallbladders are often considered to be normal, the operator, finding no stones or marked evidences of inflammation, concludes he has made an error in diagnosis. The second stage, or stage of acute biliary

---

* Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

paroxysms, is chiefly observed between the ages of 35 and 55 years. The mortality from operative treatment in this stage is from 3 to 5 per cent.

Third, a final stage characterized by acute and dangerous complications, such as empyema, or gangrene of the gallbladder, obstruction of the common bile duct, acute pancreatitis, rupture or perforation of the gallbladder, malignant disease, acute peritonitis, or intestinal obstruction from stone. These complications marking the third stage of cholecystitis are most frequently observed between the ages of 45 and 75. One of our patients was 80 years of age, seven were over 70. Unfortunately, a large proportion of patients reach the third and dangerous stage of cholecystic infection before coming to operation. That one fourth of all the operated patients of a well-known surgeon should have had associated disease of the pancreas is a sad commentary on medical delay. The occurrence of the third stage of cholecystitis is a reproach to our medical art, and indicates an average procrastination in the effective treatment of cholecystitis of about twenty years. Rather unusually, of course, we meet with exceptions. Thus during the past year I have seen one girl of 14 years with over three hundred gallstones, acute pancreatitis and fat necrosis; and a boy of 15 years with twenty-eight gallstones, localized peritonitis and a gangrenous gallbladder 7½ inches long. The mortality in this stage of cholecystitis probably averages over 20 per cent. The relief from many reflex and secondary symptoms of early biliary infection, the prophylaxis of gallstones and of the dangerous complications of cholecystitis lie in the effective treatment of the first stage of cholecystitis, and therefore the recognition of this stage deserves special consideration.

The evidence of cholecystitis of the first stage is not found in a physical examination of the upper right quadrant of the abdomen, but is to be determined by deductive reasoning. The history of the patient usually reveals a cause of infection which has a relationship to the development of certain reflex toxic, or secondary infectious processes that experience has shown frequently to express cholecystitis. These may be grouped as follows:

(*a*) Digestive: Most common are the reflex digestive symptoms. Fulness and distress after eating, with sour bitter eructations, belching, and more rarely vomiting are usual. There may be a constant foul taste in the mouth, which at once disappears when the gallbladder is drained or removed. The dyspepsia is of the "qualitative" type, rather than the "quantitative" dyspepsia of ulcer; that is, attacks of indigestion often follow certain articles of diet, such as shellfish, cheese, boiled dinners, fried foods, pastries, corn, and the like, and may not be influenced by the amount of food eaten. The patient will often mention an idiosyncrasy toward certain foods. The inability of a patient to handle certain staple articles of diet should suggest biliary disease. It is perhaps the most common condition that causes a patient to report periodically to a physician for relief from attacks of so-called biliousness or indigestion. The attacks are usually relieved temporarily by fasting, dieting, by alkalies, or by a saline or calomel course.

As to the differential diagnosis, transient, often nocturnal, attacks of indigestion in an obese, middle-aged woman precipitated by a dietetic indiscretion and requiring a hypodermic injection for relief, are rarely due to other causes than gallstones. With the history of such preceding attacks, a very violent and persistent attack suggests empyema, or gangrene of the gallbladder; while an attack of superlative severity with shock and epigastric distention and tenderness usually means a pancreatitis. As contrasted with gastric or duodenal ulcer an attack of gallstones lasts a few hours, is most abrupt and severe; an acute cholecystitis a few days and is less severe; while an ulcer attack usually lasts for several weeks and is the least severe. Between the paroxysms from stone or acute cholecystitis, which may be months or weeks apart, the patient usually has a greater degree of dyspepsia than is found between the exacerbations of ulcer. In ulcer, feeding may give temporary relief, "food ease"; while distress accompanies an empty stomach "hunger-pain." In cholecystitis and stone, food exacerbates and vomiting relieves the pain.

(*b*) Intestinal symptoms: The intestinal symptoms of cholecystitis are as yet not fully understood. The continuous discharge of bacteria laden bile into the intestinal tract may give rise to the so-called intestinal indigestion, and in some instances to the symptom of intestinal toxemia, so graphically described by Mr. Lane. It is possible that some of these patients have been given a measure of relief by the removal or elimination of the colon, not because the cause was removed, but because the absorptive surface of the intestine was reduced. There is an association between cholecystitis and appendicitis, the appendix either infecting the portal system and gallbladder, or being coincidentally infected by a common cause. Wohl has reported that in 50 per cent. of our cases in which the removed appendix was also studied, there was evidence of appendicitis.

(*c*) Peritoneal symptoms: Peritoneal symptoms result from acute inflammation or secondary adhesions. The forms of localized or diffused peritonitis that may result from the later stages of gallbladder infection require little special discussion. Attention should be directed, however, to the frequent error in mistaking cholecystitis for appendicitis. An enlarged inflamed gallbladder, with only a small area of the fundus projecting below a Reidel lobe of the liver, frequently produces recognizable peritoneal inflammation only when the exposed fundus comes in contact with the sensitive parietal peritoneum, and this frequently is directly under McBurney's point. In nearly every such instance which we have seen, the examiner, overlooking the less distinct and less sensitive area of resistance which spreads down from the right costal border, has concluded that acute appendicitis was present.

(*d*) Arthritic and muscular complications: Subacute or acute metastatic joint infections are frequently observed in chronic cholecystitis. Often these symptoms improve after cholecystectomy. Chronic joint changes of the type of arthritis deformans are also observed. Myalgic pains are exceedingly common.

(*e*) Cardiovascular symptoms: Few patients pass to the third stage of cholecystitis without some evidence of cardiovascular disease. Endocardial and particularly myocardial changes seriously increase the risk of anesthesia and of operation in long-standing gallbladder disease. To some degree pathologic changes of the arterial wall also have their origin in cholecystic infections. Cardiovascular symptoms may greatly improve after operations on the gallbladder.

(*f*) Respiratory symptoms: We have been impressed by the surprising relief from paroxysmal cough and asthma that may follow cholecystectomy, or cholecystostomy, and we have operated for these symptoms alone. Two of our patients who had been unable to sleep except in a sitting posture for five and seven years, respectively, found they could recline with comfort after the operation, and the asthma and cough disappeared. After a period of relief for some weeks, however, the symptoms recurred. It would seem that cholecystic toxemia is a factor in some of these cases.

(*g*) Cerebrospinal symptoms: In cephalalgia, neuritis and some of the neuroses relief may be obtained by operating on the gallbladder. In the so-called bilious sick headaches we have observed relief after cholecystectomy, and in one violent case we operated for this symptom alone, with relief. In this case the symptom was a sequence to typhoid fever. In certain of the prematurely worn women of middle age, who constantly complain of indigestion, bloating, constipation and a multitude of aches, pains and surface paresthesias, there has been something of a mental transformation after the removal of a chronically infected gallbladder.

(*h*) Fever: Fever without other symptoms may result from cholecystic infection. The bile may be free from pus, the gallbladder bluish and nearly normal in appearance. The fever disappears with the removal of the gallbladder. One of our patients with no local symptoms had been treated in hospitals for months for an apparently causeless continuous fever, that immediately subsided after the excision of what seemed like a normal gallbladder.

(*i*) Eye symptoms: Eye symptoms are not infrequent with biliary disease. At times we find the oculist promising relief from the digestive symptoms of cholecystitis by the application of glasses, or, again, vainly attempting to control a vacillating series of refractive or muscular abnormalities.

DIAGNOSIS

The diagnosis of cholecystitis after opening the abdomen is not always easy. We depend on one or more of the following abnormal conditions:

1. Alteration in the color, size or consistence of the walls of the gallbladder. A milky or whitish gallbladder is diseased, but many translucent, bluish gallbladders are also diseased.

2. Adhesions or other evidence of pericholecystitis. Often the liver adjacent to the gallbladder shows evidence of chronic perihepatitis by whitish plaques or connective tissue trabeculation.

3. Enlargement of tributary lymph nodes: Attention has been especially directed by W. J. Mayo to the lymph nodes. The palpating finger is introduced into the foramen of Winslow and the nodes near the junction of the cystic and common ducts examined. While such lymph-node enlargements usually indicate cholecystic infection, they may also occur from pancreatic or duodenal disease. Absence of enlargement unfortunately does not negative cholecystitis. At times we have observed the absence of adenopathy in purulent or gangrenous as well as in catarrhal cholecystitis.

4. Alterations in the bile contained within the gallbladder: Normal bile is of a clear golden yellow color; turbid, purulent, dark green, tarry bile, or bile containing crystals, sand or calculi, indicate cholecystitis. Colorless mucus indicates cystic-duct obstruction and a mucocele. For diagnostic aspiration, to avoid leakage, should the gallbladder not be removed, a fine needle should be introduced into the gallbladder through a thin layer of overlying liver substance.

5. Alterations in the mucosa: Papillary denudations producing the finely speckled or strawberry gallbladder, papillary outgrowths, infiltrations of the mucosa as well as the grayish, greenish or blackish wall, or sloughs seen in empyema or gangrene, indicate varying grades of gallbladder disease.

PROGNOSIS

Cholecystitis may be alleviated by dieting, alkalies, salicylates, vaccines or a saline or Carlsbad course. It is more surely curable by the operative removal or obliteration of the mucous lining of the gallbladder. Most patients who finally come to operation have had some degree of relief from dieting, or various medical measures. In a woman who, for six years, following typhoid fever, had suffered from indigestion, headaches, myalgia, bromidrosis and foul taste, the symptoms almost completely disappeared after a course of typhoid vaccines. Except in the third stage of cholecystitis which brings an immediate danger to life, operation is usually delayed or considered unnecessary. At present, surgery, which is about the only permanently effective therapeutic measure against cholecystitis, is about twenty or thirty years behind the pathology of the disease, usually ignoring the early stages of inflammation and cholecystic toxemia, permitting years of morbidity and crippling tissue changes to supervene, and only intervening when a violent local reaction drives the patient to the surgeon.

OPERATIVE TREATMENT

Anesthesia: An anesthetic may increase the danger of operation on the biliary tract by depressing the cardiac and respiratory systems, adding to the preexistent toxemia, inhibiting elimination, and by producing straining movement, violent respiratory action and rigidity of abdominal muscles, that so embarrass the surgeon as to invite dangerous technical errors. At the Samaritan Hospital during the past three years, one patient with a perforated gallbladder and an upper abdominal peritonitis, was asphyxiated by profuse, regurgitant vomiting, while under spinal and narcotic anesthesia. In a second patient with myocarditis, cholecystitis and acute peritonitis there was a fatal respiratory cardiac failure. A third similar fatality occurred under the administration of ether. We have been able to reduce the mortality by substituting local anesthesia for patients who are bad risks. The local anesthetic solution is used very freely, 1 per cent. of novocain being employed for the skin and subcutaneous tissues, and a 0.25 or 0.5 per cent. solution being employed for the muscular, fascial and peritoneal layers. A free injection of such weak anesthetic solutions seems not only harmless but often beneficial, acting like a hypodermoclysis in assisting elimination. If the patient's general condition permits, a moderate supplemental narcosis produced by morphin-scopolamin is used. Especially in the very old, the very toxic or asthenic with empyema or gangrene of the gallbladder, or perforation and peritonitis, do we prefer local anesthesia. For patients in better physical condition, we prefer spinal anesthesia because it does not interfere with elimination or increase preexisting toxemia, and at the same time gives far better relaxation than ether does. It is dangerous for operations on the gallbladder in obese elderly patients who are toxic and have serious myocardial change. Rectal anesthesia, from its especially intense action on the liver, should be avoided.

Incision: A simple transverse incision made along a line slightly below the level of the ninth rib is valuable when operating under local anesthesia, especially if the gallbladder is large and there is marked muscular rigidity. In such a case the gallbladder and liver margin may be made to protrude from the opening and retraction and the introduction of pads within the abdomen are unnecessary. It is especially adapted for cholecystostomy, although occasionally a cholecystectomy may very conveniently be done. For the former operation a shorter incision may be employed, the different layers being divided along the same line. To give a better exposure of the ducts, a triangular flap incision, as suggested by Perthes, may be used. A right transrectus incision is made from the ensiform directly downward for 3 or 4 inches, from the lower end of this vertical incision a transverse incision is made to the right to a point just below the right costal margin. The vertical part of the incision is carried through the rectus to the posterior sheath and guided by the finger introduced behind the rectus fibers; two or three sutures of catgut are placed above and below the line of the transverse incision in such a manner as to fix the rectus muscle to the overlying aponeurosis, so that the divided muscle will not retract. The muscular and aponeurotic layers are now divided along the line of the transverse incision and the triangular flap thus formed turned upward and outward over the chest wall. The peritoneum and preperitoneal fascia are now divided along a line parallel with the costal border and about one-half inch distant from it. To avoid the objectionable right-angle incision of the skin, I have modified Perthes operation by substituting a simple oblique skin incision which is made parallel with the costal border after the plan of Kocher.

Alexander Don, to obtain a greater exposure and to avoid injury to the intercostal nerves, extends the vertical portion of the incision down to the level of the navel, and curves the transverse portion of the incision upward and outward toward the right axilla. The rectus muscle is completely freed and divided below and the posterior sheath of the rectus and peritoneum divided along the same lines as is the skin.

In patients with relaxed or thin abdominal walls a simple vertical transrectus incision often serves very well.

Cholecystectomy: In the first stage of cholecystitis, cholecystectomy is the preferred operation. It is the most effective method of treating the protean manifestations of the disease. The patients are usually under middle age, are not very obese and come to the operating table in good physical condition. With a perfect technic the operation in this stage should be a safe and satisfactory one, but unfortunately there are serious technical dangers always present in doing a cholecystectomy; an unfortunate snip of the scissors, a careless needle puncture or an imperfect ligation, is all that is required to place the patient's life in jeopardy, and these accidents have caused many surgeons to resort to ostomy when an ectomy would be the better operation. Even so skilful an operator as Moynihan reports three cases in which an hepatic or common duct was wounded. In my first ectomy, a case in which there were extensive intra-abdominal adhesions, the divided cysticus was imperfectly occluded and a secondary fatal leakage of bile into the peritoneal cavity occurred. In a recent case the gallbladder was distorted and displaced by adhesions, and on closing the peritoneal edges over the gallbladder bed, biliary leakage, evidently from a punctured displaced hepatic duct, occurred. The stitches were removed and drainage was instituted, with recovery. We have had three other cases of accidental duct injury or imperfect ligation of the cystic duct during cholecystectomy. These accidents are less frequent when the operation is performed in the first stage of cholecystitis. Since the first case we have now had 114 ectomies during the first stage of cholecystitis without operative mortality. In this stage the gallbladder is usually best removed from within outward, after the method so well illustrated by the Mayos. The cystic duct should be doubly ligated, mass ligatures should be avoided, as should anything which may serve to distort or obstruct the ducts. The cystic artery should be individually tied. Wide flaps of peritoneum should be separated from the gallbladder to cover the denuded area left under the liver. If there is any question as to absolute hemostasis or duct occlusion adequate drainage should be employed, so arranged or anchored by fine catgut that it cannot be displaced. In most of our ectomies we have been able to avoid all drainage. In cases of the second or third stage when the gallbladder is distorted or imbedded in adhesions, it may be safer to remove the gallbladder from without inward. In this way, by hugging the gallbladder very closely, there is less danger of damaging the hepatic or common duct. In case the adhesions are very marked, the method of Kehr of first splitting down the interior surface of the gallbladder at least into the cystic duct, is an advantage in determining the relationships of the parts.

Cholecystostomy: External biliary drainage, considered by the late Dr. Maurice Richardson only ten years ago, the one established therapeutic fact in biliary surgery, has a progressively lessening sphere of usefulness. Its use should be largely restricted to the third stage of cholecystitis for cases of empyema, perforation, gangrene, pancreatitis, advanced peritonitis or duct involvement, associated with such grave systemic changes due to age, toxemia or exhaustion, that only the simplest of operative procedures are warranted. It also should be used when technical limitations indicate that an ectomy will be dangerous. Under certain favorable conditions by performing cholecystectomy, we have been able to avoid drainage even in cases of empyema, gangrene of the gallbladder and acute pancreatitis. As a rule, the virulence of the bacteria found in empyema or gangrene against the skin and subcutaneous tissues is less than that of the bacteria found in purulent forms of appendicitis.

As cholecystectomy is the great measure of prophylaxis, it should be performed more frequently and much earlier and should have a progressively lower mortality than cholecystostomy.

If reasonably safe and feasible the appendix should also be removed in operating for cholecystitis. Despite certain results of animal experimentation, clinical evidence indicates that a patient is better off without than with a chronically infected gallbladder.

MORTALITY

The mortality of cholecystectomy is due to: 1. Poor judgment in selecting patients with acute febrile and septic conditions, or patients greatly debilitated by age, chronic toxemia or complete and continued external drainage of bile. This latter class who have what we may term "cachexia-choleoprivia" bear operation very badly, readily falling into a condition of fatal shock irrespective of the operation or anesthetic employed. For them a simple Witzel enterostomy should first be done under local anesthesia and the bile shunted from the fistula into the bowel by a small rubber tube. The final operation should be delayed until the cachexia, due to the loss of bile, has been overcome.

2. Technical errors: Leakage of bile into the peritoneal cavity may result from the cystic duct having been imperfectly tied, or the common or hepatic duct torn, incised or punctured. In the case of bile leakage, if the general peritoneal cavity is not sufficiently protected by drainage and tamponade, a dangerous or fatal peritonitis may result. I have been impressed by the danger of (*a*) doing cholecystectomy in a private house where adequate light and sufficient exposure cannot be obtained; (*b*) separating the overhanging neck of the gallbladder without observing great care in hugging the gallbladder proper to avoid the adjacent communis; (*c*) puncturing the hepatic duct. The gallbladder may lie obliquely so that the hepatic duct is in the peritoneal fold to the side of the neck of the gallbladder, where it may be damaged in suturing over the gallbladder bed; (*d*) relying on insufficient tamponade for drainage in the presence of a biliary leak. In all cases, as an indicator, we place the end of a gauze sponge against the stump of the cystic duct, which is not removed until the end of the operation. Should this show staining by bile, we immediately reopen and control or isolate the area.

In a personal experience of 270 operations on the gallbladder and ducts, fifty-seven ectomies were done before 1912 with ten deaths, a mortality slightly over 17 per cent. In thirty-eight ostomies before 1912, there were three deaths, a mortality of 7.8 per cent. In 121 ectomies performed since 1912, there were two deaths, a mortality of 1.6 per cent. In forty-two ostomies since 1912 there were four deaths, or about 9 per cent. mortality. Before 1912, gangrenous and suppurating gallbladders were usually removed; now they are usually drained under local anesthesia. As having even a greater influence on the mortality is the stage in which the operation is done. In 114 cases of ectomy in the first stage of cholecystitis, irrespective of date or technic, the mortality was 0.88 per cent. In 101 operations in the second stage, sixty-seven being ostomies, there were four deaths, a mortality of 3.9 per cent.; while after fifty-four operations in the third stage of cholecystitis, there were eighteen deaths in which the operation or biliary condition was a factor, a mortality of about 32 per cent. Thirty of these patients had acute gangrenous or suppurative cholecystitis, seven an acute pancreatitis with fat necrosis. Twelve had primary or secondary operations for duct obstruction, fistula or duct or intestinal anastomosis. In only one patient was carcinoma observed, and this involved the ducts. In two cases, intestinal obstruction from gallstone existed. In another case an intestinal perforation had been produced. One death was from diabetic coma and one from pulmonary embolism. It is evident that the stage of the disease is more important than the type of operation in determining the mortality.

SUMMARY

We consider inflammations of the gallbladder as bacterial infections of childhood or early adult life, as progressing for years, during which time secondary metastatic, toxic or reflex symptoms only are observed; as later having a second stage in which there are attacks of colic due usually to the presence of gallstone; as having usually after twenty or thirty years a third stage of serious complications, such as duct obstruction, pancreatitis, perforation, abscess or gangrene. We consider surgery as working, for the most part, far behind the pathology of the disease, and believe there is wide need for earlier intervention, so that the patient who starts at the age 12 or 15 with cholecystitis and dyspepsia may not at 35 have gallstone colic, and may not at 65 succumb to cholecystic gangrene or pancreatitis. We consider external biliary drainage as a rule undesirable, except in the late or complicated cases, an early cholecystectomy the operation of choice. Unfortunately, technical dangers make uniform success after cholecystectomy uncertain in the hands of the average surgeon. Despite this, the mortality of cholecystectomy in the first stages of cholecystitis is much less than cholecystostomy in the last stages of this disease, so that the results of a surgeon may depend more on *when* he operates than *how* he operates. The morbidity depends on *how* he operates.

2033 Walnut Street.

ABSTRACT OF DISCUSSION

Dr. Robert C. Coffey, Portland, Ore.: In dealing with third stage, acute stage cases, in which there is an infected gallbladder, I wish to emphasize conservatism. It is often the case that these gallbladders may be enucleated by a simple incision of the peritoneum and peeled out practically without bleeding at all. There are some cases, however, in which this is not advisable. I refer to acute and violent septic cases. The point I wish to emphasize particularly is that this area must be quarantined properly. Expose the field thoroughly and place a large pack of gauze wicks laid straight down around the gallbladder, and around these wicks several layers of rubber tissue. Open the gallbladder, sponge out the fluid and insert a piece of gauze into the gallbladder. That is all that is necessary. It will take approximately five minutes. Many are gangrenous without widespread infection and it is quite safe, in these, to enucleate the gallbladder, which I say is easily done without hemorrhage at all. The gauze wicks of the pack are removed after six days and the rubber tissue in two weeks. In some instances it will be necessary to remove the gallbladder at a later operation.

Dr. W. Wayne Babcock, Philadelphia: In the young no drain may be required after ectomy. There is less danger of skin infection from removal of the gangrenous or suppurating gallbladder than from removal of a badly infected appendix, and therefore as far as wound infection goes, less need for wound drainage. When the patient is in good general condition, we may, therefore, in selected cases remove the badly infected gallbladder, close without drainage, obtain primary union, and a remarkably quick recovery. One patient went home a week after the removal of a gangrenous gallbladder. But as a rule, and especially if the patient has reached middle age and the gallbladder is gangrenous, ectomy is dangerous. In these cases we use local anesthesia, make a simple transverse slit, put in a drain, and sometimes even operate without removing the patient from the bed. The sloughs of the gangrenous gallbladder will be expelled with relative safety, while the removal of the gallbladder, by opening many lymph spaces, may be followed by rapid sepsis and overwhelming toxemia.

ALBERT H. ROWE, M.S., M.D.
CAMBRIDGE, MASS.

The microrefractometric method recently described by T. Brailsford Robertson[1] has enabled us to determine the amount of albumin and globulin in normal human serum. The specimens of serum which we have employed for this purpose have been obtained from students, nurses and doctors working in the hospital, who are in good health. No serums of patients have been used to establish these normal valuations.

In brief, the method is as follows: Blood is drawn into centrifuge tubes, allowed to clot, and centrifugalized. A portion of the clear serum is treated with an equal volume of saturated ammonium sulphate to precipitate the globulins, and the precipitate removed by centrifugalizing. The clear fluid is diluted to one-half and read in the refractometer. This reading, corrected for ammonium sulphate, gives the total albumin plus the nonproteins. The nonprotein value is determined from the clear fluid remaining after the proteins have been removed from another portion of the serum by heat and acetic acid. The total globulins are obtained by subtracting the refractometric reading of the albumins from that of the whole serum, after deducting the value of the nonproteins.

Emil Reiss has carried out extensive refractometric determinations of the total proteins of serum in normal as well as in pathologic cases. A monograph[2] containing a full account of his entire work and references to a great number of articles by other writers appeared about two years ago, and recently he has published a brief review[3] of this work, including that of the last two years.

Reiss obtains only the value of the total proteins in his work. In estimating this single value, moreover, Reiss considers the nonproteins constant enough, even in pathologic cases such as nephritis and diabetes, to give them a set value having a refractive index of 0.00277. Robertson has always considered this value too high, and has assumed that a more accurate constant value is obtained from the reading of sixth-molecular sodium chlorid, thus placing it around 0.00157.

At the beginning of our work, we saw the necessity of the individual estimation of the nonproteins in each pathologic case to assure accuracy. We have, therefore, determined the nonproteins or normal serums, giving us an average value of 0.00175. This is considerably lower than the value of Reiss, and lies nearer that assumed originally by Robertson. If it is desired to express the concentration of the nonproteins in percentages, this may be done with sufficient accuracy by dividing their observed refractivity by the constant factor of 0.00160. Many observers in cases of nephritis have shown increased percentages of nonproteins as compared with the normal. Thus, even in normal cases, about 0.6 per cent. error occurs when the constant value of Reiss for nonproteins is used, and it is evident that when the pathologic cases are dealt with, the error would be considerably greater. It is true that the method of Reiss is much simpler than that of Robertson, and that his error is not excessive. Yet the data obtained by the latter method gives not only an accurate determination of the total proteins as well as of the nonprotein elements, but also the amounts of albumin and globulin which go to make up the total proteins.

In normal individuals we have found that:

1. The total proteins range between 6.7 and 8.7 per cent., which corresponds to the figures of Reiss, which, he says, lie "in round numbers between 7 and 9 per cent." The average value equals 7.94 per cent.

RESULTS IN NORMAL CASES

* In this column, ♂ indicates male, and ♀ female.
† This serum is not used to get average values.
‡ This subject had boils six months ago, though physical examination is negative now.
§ This man had eaten very little for several days.

2. The total albumins lie between 4.95 and 7.7 per cent., with an average value of 6.20 per cent., or between 67 and 89 per cent. of the total proteins, with an average value of 78 per cent.

3. The globulins lie between 1 and 2.54 per cent., with an average value of 1.74 per cent., or between 11 and 33 per cent. of the total proteins, with an average value of 22 per cent.

4. The nonproteins lie between 0.98 and 1.19 per cent., with an average of 1.09 per cent., and have a refractivity varying from 0.00158 and 0.00190, with an average of 0.00175.

The first seven results in the table are of interest. The first three were taken from the same person on the same day, the first immediately on awakening, the second four hours after breakfast, and the third one hour after a hearty meal. The first two results are practically the same. The third result shows an increased proportion of albumin to globulin. Robertson[4] has observed that fasting in the rat produces an increase in the proportion of globulin in the blood serum, while our one observation gives an increase in the proportion of albumin soon after a hearty meal. This supplies an instance of the value of estimating the ratio of albumins to globulins. No peculiarity would have been discovered in this serum if Reiss' method had been used. The fourth and fifth serums and the sixth and seventh serums were taken from two subjects on different days at a time from three to four hours after breakfast, and no essential differences on different days were found. From this we conclude that, in order to obtain comparable results, blood should be taken from patients under comparable conditions. The specimens of blood used to establish our normal values have been taken either before breakfast, or from three to four hours after meals. (Serum 3 was not used in the calculation of the averages.) No appreciable amount of muscular work had been done immediately before the experiment by the subjects from whom we withdrew blood. We considered it unnecessary and unpractical to establish our normal from persons who had been in bed for twenty minutes before the withdrawal of the blood, as Reiss[3] advises.

---

[3] Reiss: Deutsch. Arch. f. klin. Med., 1915, cxvii, 175.

No definite differences can be noticed in the results due to the age of the subjects. The percentage of globulin is consistently higher, however, in the women examined than in the men.

We have attempted in this series to give the mean values of the proteins in normal healthy subjects, and to indicate the normal variations above and below the mean. More observations are needed to bring out fluctuations due to such factors as diet, starvation and muscular effort.

Work in diseased conditions is to follow.

IMPORTANCE OF THOROUGH EXAMINATION IN UROLOGIC CASES*

A. J. CROWELL, M.D.
CHARLOTTE, N. C.

In presenting this paper, I desire to illustrate and emphasize the value of the use of every available aid at our command not only from a diagnostic but also from a therapeutic standpoint. For this purpose, I will briefly report a series of cases which lately came under my observation.

The first series is that of stone in the ureter and kidney; second, pyogenic infection; third, new growths, and fourth, tuberculosis.

It would be impossible to discuss any one of these conditions fully in the time allotted me, therefore these cases will be used only to illustrate and emphasize a few cardinal principles in the diagnosis and treatment of these cases.

Of the twelve cases of stone (nine ureteral and three kidney) I shall use for this purpose, five were reported negative from the Roentgen-ray department. These were in the ureters and were located by the use of the ureteral catheter. The first was lodged about 1 inch above the ureterovesical opening. Two unsuccessful efforts were made to dislodge it with the ureteral catheter and sterile oil. A suprapubic cystotomy was performed, the ureteral opening enlarged and the stone removed through it with some difficulty.

In the second case, in which the Roentgen ray was negative, the stone was twice located with the ureteral catheter about 3 inches below the kidney pelvis and two unsuccessful efforts were made to dislodge it. A left rectus incision was made and the peritoneum deflected from the left abdominal wall all the way from the anterior incision back to and over the ureter, and the stone was removed through a small ureteral incision. A cigaret drain was inserted through a stab wound in the back and the patient made a rapid and uneventful recovery.

The Roentgen ray was also negative in the third case, but the stone was located and dislodged by catheterization. The patient suffered several typical attacks of nephritic colic for six months before she was referred to us. In this case the left ureter was catheterized without difficulty and found to be functionating normally, but a decided obstruction was encountered in the right ureter 4 inches above the ureterovesical opening. This was finally passed and 8 ounces of urine were withdrawn from this kidney before it began functionating intermittently, which, of course, demonstrated a hydronephrosis. The catheter was then withdrawn below the point of obstruction and 2 c.c. of a 2 per cent. solution of cocain were injected. The latter was done with the hope that a relaxation of the muscular fibers of the ureter might be obtained and in this way the passage of the stone into the bladder secured. Relief followed, and on cystoscopy the second day thereafter, the stone was seen in the bladder.

There may yet be uric acid stones in this kidney, but the value of the ureteral catheter was forcibly demonstrated here, not only from a diagnostic, but also from a therapeutic standpoint, since we were enabled to dislodge the calculus and cause it to pass into the bladder.

The fourth case was that of ureteral stone producing the usual symptoms for two weeks previous to the time the patient came under my care. This we easily located with the Roentgen ray about 6 inches above the vesico-ureteral opening. The ureteral catheter was used here not only to verify the Roentgen-ray findings but to dislodge the stone if possible. Following the second ureteral catheterization, the injection of cocain and oil, the stone passed into the bladder and the patient, a physician, was spared an operation.

In the fifth case, the Roentgen-ray findings were negative. The symptoms were typical of nephritic colic. Firm percussion over the left kidney was unbearable. These symptoms had persisted for six days.

On ureteral catheterization, obstruction was encountered 9 inches above the ureterovesical opening. No urine was secured until this point had been passed, when 20 c.c. of a bloody urine were withdrawn.

The same procedure was followed in this as in the above-mentioned cases. The patient was prepared for operation the following day, but cystoscopy, before administering the anesthetic, enabled me to demonstrate to my associates the cause of the greatly improved condition of my patient. The bladder was dotted with fragments of stone—one yet remaining in the ureteral opening. This was removed with the beak of the cystoscope.

---

[4] Robertson, T. B.: Jour. Biol. Chem., 1912, xi, 179; ibid., 1912, xiii, 325.

* Read before the Section on Genito-Urinary Diseases at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

In four other cases of ureteral stone—one of which was reported negative from the Roentgen-ray department—the patients were treated in the same way, but unsuccessfully with two. These stones had to be removed by operation.

The two cases in which this plan failed were not suitable for this procedure. The ureteral occlusion had persisted sufficiently long to inhibit the kidney function. This is very important, since the pressure behind the stone is kept up by kidney functional activity and forces the stone into the bladder while the muscular fibers of the ureters are under the influence of cocain.

Of these nine cases, the Roentgen-ray findings were negative in five and the diagnosis was made with the cystoscope, ureteral catheter and by means of the typical clinical symptoms. In the remaining four cases the Roentgen-ray findings were verified and five of the nine patients were spared operation.

Another valuable aid in diagnosing ureteral and occasionally pelvic stone is the wax-tipped ureteral catheter. Scratches in the wax made by them can easily be detected with a magnifying glass.

In all the cases of kidney stone in this series Dr. Squires was able to demonstrate them by roentgenography. In these, we found the ureteral catheter, in connection with the phenolsulphonephthalein test, of incalculable value in ascertaining the amount of kidney destruction produced by them and in determining the best surgical procedure to pursue. To illustrate, I will briefly report three cases of kidney stone which show the different degrees of destruction produced by them.

The first was a case in which there was a small stone in the kidney pelvis. Ureteral catheterization showed only a slight pyelitis and its functional activity normal. No kidney tissue had been destroyed. The stone was removed by pyelotomy. There was practically no leakage of urine following the operation.

In the second case the stone was much larger, extending considerably into the kidney parenchyma. Urine obtained by ureteral catheterization indicated only a moderate amount of pyogenic infection, but the phthalein test indicated considerable kidney destruction. In this case the stone was so large, though there was only a mild infection, that we decided nephrectomy advisable since it would be impossible to remove the stone without lacerating the kidney considerably in so doing. This would almost certainly be followed by a return of stone formation.

The third case was one in which we not only had to deal with a large stone, but active infection as well. The phenolsulphonephthalein output from this side was very poor. In this and the preceding case, the phenolsulphonephthalein output of the opposite kidney was good and we had no hesitancy in removing the stone-bearing kidney. These patients seemed to suffer no inconvenience following nephrectomy and made excellent recoveries.

Of the great number of cases of pyogenic infection which have fallen into our hands, I shall, instead of reporting individual cases, speak of the types of most importance and the means of arriving at a diagnosis and of ascertaining the plan of treatment that should be instituted. (Deviating a little, I will say that the channel through which infection takes place in these cases depends principally on their predisposing causes, that is, whether it occurs through the hemic or lymphatic circulations or by ureteral ascent. The majority of the parenchymatous infections, of course, is through one of these circulatory systems and the source of such infections may be in any part of the body. The predisposing causes of infection through the urinary bladder are stricture, hypertrophy of the prostate, or any condition or disease interfering with the normal elimination of the urine. To ascertain, then, just the nature and extent of these various infections, ureteral catheterization, functional activity tests and bacteriologic examination of urine thus obtained is absolutely necessary, not only from a diagnostic standpoint, but also for the purpose of securing bacteria for autogenous vaccination. An ascending infection with normal ureters practically never occurs, as the urine is constantly flushing the ureters from above downward. In this way nature protects herself. But with residual urine, infected bladder and dilated ureters, ascending infection is very common.)

An idea as to the location of pathologic conditions in the urinary tract may be obtained by the ordinary chemical and microscopic examinations of the bladder urine, but to ascertain definitely the location and extent of these, the ureteral catheter and functional tests are absolutely indispensable. Pus in urine thus obtained means infection and the extent of this infection, that is, whether it be limited to the pelvis or extend into the parenchyma of the kidney, may be ascertained by the quantity of pus thus secured and the functional activity ascertained by the phenolsulphonephthalein test. For instance, if we have a pyelitis, pus and blood are secured by ureteral catheterization, but the functional activity is normal. The exciting cause of this pyelitis may be ascertained by bacteriologic examination. If the secreting portion of the kidney is involved as well, then the functional test will be affected in proportion to the amount of kidney destruction.

An illustration of the value of ascertaining the phenolsulphonephthalein output is shown in the following case of tumor of the kidney.

Mr. B. H., aged 38, consulted me for intermittent painless hematuria. The ureters were cathetrized and I found that the blood was coming from the right kidney, but no pus was secured. The phenosulphonephthalein output was about normal and the two kidneys equal in their secretory power. The patient presented himself from time to time for examination extending over a period of eight or ten months. With each subsequent ureteral catheterization the output of the right kidney grew less and that of the left greater until it was more than double that of the opposite kidney. The diagnosis of hypernephroma was made. The kidney was finally removed and the diagnosis sustained by the pathologist.

Several cases of hypernephroma have fallen into my hands but none so early and in which the progress was watched so closely or the value of the phenolsulphonephthalein output so forcibly demonstrated as in this case, but in all of them it has been in proportion to the kidney parenchyma destruction.

Two cases of tuberculosis of the kidney illustrate, first, the importance of recognizing and properly interpreting its early symptoms; second, some simple methods of making accurate diagnosis, and third, points of value which will aid us in determining our plan of treatment.

The first case is that of early primary tuberculosis. This was referred to me as one of subacute cystitis, the symptoms probably being augmented by bladder stone. Urination was frequent both day and night, from the beginning. This, with only a small amount of pus and practically no blood, at once led us to suspect tuberculosis of the kidney. Cystoscopy showed marked congestion of the trigon with slight ulceration around the right ureteral opening. Urine obtained from this kidney showed the presence of a trace of albumin, a moderate amount of pus cells and an occasional blood corpuscle. A centrifugalized specimen was injected into the peritoneal cavity of a guinea-pig. A specimen was also stained and tubercle bacilli found. The patient could not be operated on at once but returned in five weeks for this purpose. At that time the pig was killed and the peritoneum, liver and kidneys were found to be filled with tubercles.

The patient's kidney was removed and the lower third found to be filled with small tubercles, but with no abscess formation. His urine, which had previously been filled with pus, immediately cleared up and the bladder symptoms subsided. The patient gained 25 pounds in weight in two months. At present, twelve months after, there is no evidence of tuberculosis anywhere in the body and the patient is in excellent health.

The second case was one of two years' standing. The patient suffered intensely with cystitis and lost 93 pounds in weight during this time. On account of extreme sensitiveness of the bladder and its decreased capacity, ureteral catheterization was accomplished with much difficulty. In fact, several efforts were made before we succeeded in catheterizing his left ureter. An ulcer, located at its opening, made it unusually difficult.

The urine secured from the right kidney was filled with pus and tubercle bacilli. The phenolsulphonephthalein output was very poor. No bacilli, pus or blood were found in the urine from the left kidney, but tuberculous peritonitis was produced in a guinea-pig with urine from this, as well as from the right. These bacilli probably came from the ulcer at the ureteral opening. With a negative urine, however, a 40 per cent. phenolsulphonephthalein output of the opposite kidney the first hour, and with the great probabilities of this kidney becoming involved, if it had not already become so, I had no hesitancy in removing the right kidney. This was done six months ago; the patient rapidly gained in weight and strength and his bladder symptoms wonderfully improved in a very short time and he is now free from suffering and apparently a well man.

In determining kidney functional activity we have found blood urea estimation in connection with the phenolsulphonephthalein test of incalculable value. It is of especial service following prostatectomy. In these cases, the urine cannot be accumulated to estimate the phenolsulphonephthalein output and the blood can always be obtained and the urea retention estimated.

Of all the functional tests we have used, we find ourselves relying more and more on these two and in our experience, as the phenolsulphonephthalein increases, the urea decreases and vice versa. The latter furnishes evidence of impending uremia but it should always be used as an adjunct, since the determination of the cumulative phenomena is of great prognostic value, although its absence may be misleading, which makes it necessary to ascertain the combined results of these tests.

CONCLUSIONS

1. Every available means should be employed for diagnosing and determining the best therapeutic measures to pursue in diseased conditions of the genito-urinary tract.

2. The majority of ureteral stones can be removed by the injection of cocain and oil, provided the ureters are normal and it is done soon after impaction.

3. The kidney functional tests, especially phenolsulphonephthalein and blood urea, are of the utmost importance in determining the condition of the kidneys before operation, and that after prostatectomy, the blood urea, which must then be used alone, is of the greatest value.

Realty Building.

THE MECHANISM OF URINATION*

ARTHUR B. CECIL, A.B., M.D.
LOS ANGELES

The mechanism of urination has not been determined in all its detail, but a large amount of work has been done, and by correlating the work of the anatomist and the physiologist with that of the clinician, the physiology of urination can scarcely longer be regarded as problematic.

Enough has been determined to be of great assistance in the diagnosis of diseases of the urinary tract, and to establish definite principles of inestimable practical value in genito-urinary surgery.

It must be admitted that many of the unsatisfactory results following operations on the bladder neck and urethra have been due to a disregard for the underlying principles of the physiology of the mechanism of urination.

It is the purpose of this paper to present in a correlated form the present status of knowledge of the act of urination, together with some observations which I have carried out on the physiology of the bladder and urethra.

The nervous mechanism is especially complex and interesting. For a number of years it has been maintained that in animals, at least, there are centers of urination outside of the spinal cord. Experiments of Sokowin (1784), Nussbaum (1879), Nawroki and Skadichewaki (1891), and Justchenke (1897), have demonstrated that the inferior mesenteric ganglion contains a reflex center for vesical contraction.

Von Zeissl,[1] from his researches, concluded that there are centers for urination within the bladder wall itself. This observer divided all of the nerves to a dog's bladder, that is, completely isolated the bladder from the central nervous system, and the sympathetic ganglia of the pelvis, and in spite of this the animal retained urine and emptied the bladder in a normal manner.

---

* Read before the Section on Genito-Urinary Diseases at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

[1] Von Zeissl: Ueber die entnervente Blase, Wien. klin. Wchnschr., 1896, ix, 394.

Goltz and Ewald[2] removed the sacrolumbar cord and part of the dorsal cord in dogs and after a short time they found that the bladder emptied itself regularly at definite intervals.

In 1901, Muller,[3] from his observations and experiments, arrived at the conclusion that the reflex centers of urination are not situated in the spinal cord at all, but are exclusively placed in the sympathetic ganglia. Muller extirpated the cord in four dogs, and according to him, after a few weeks the bladder showed automatic functioning, without leakage in the interval between voidings. He ascribed to the spinal cord only trophic centers.

The new idea, as brought out by Muller, seemed to completely overthrow the classical views as to the physiology of the conus terminalis, and his views have been accepted by a large number of observers, while others, though admitting the existence of sympathetic centers, have superimposed on them the spinal center. It is still a difference of opinion, among this latter group, as to whether the sympathetic centers are capable of carrying on normal reflex vesical function after destruction of the conus terminalis or cauda equina.

Van Gehuchten considers that the sympathetic centers can functionate independently of the cerebrospinal centers.

Oppenheim, on the other hand, claims that the reestablishment of the vesical rectal function by the sympathetic centers takes place in a wholly imperfect manner.

The researches of Roussy and Rossi[4] on monkeys and dogs to determine the location of the bladder center and the effect of various lesions of the conus terminalis on the bladder function, are most interesting and convincing. In a certain number of animals they completely removed the conus terminalis or divided all the nerves of the cauda equina.

In another series they divided the spinal cord above the conus. In animals in which they destroyed the conus terminalis, or divided the cauda equina, there was complete paralysis of the bladder and its sphincters. Urine leaked from the bladder, drop by drop, as it entered it, or there were passages of small quantities coincident with movements of the animal, such as barking, etc. So that in these animals there was a picture of the atonic bladder, and this persisted during the life of the animals, many of which were kept alive for several months.

There was no such resuming of the bladder function as had been described by those who claimed the location of the bladder center to be outside of the spinal cord.

In those animals in which the cord was divided above the conus there was at first, for about three days, complete retention of urine. After this urination took place during the whole life of the animal in streams of urine with definite intervals without, as a rule, loss of urine in the interval.

The bladder resumed a reflex periodic emptying. They, therefore, concluded that the so-called sympathetic centers are utterly incapable of resuming, in anything like a normal manner, the function of the bladder when these centers are isolated from the spinal cord, and that the true center of urination lies within the conus terminalis.

They do not deny, however, the existence of extraspinal centers or the existence of centers within the bladder wall itself. But it would seem that they did definitely establish that these centers cannot carry on vesical function independent of the spinal cord.

The course of the peripheral nerves has been worked out by a large number of anatomists and physiologists, and the essential facts are now well established. In general, motor fibers are found in the second and third sacral roots and in the nervus erigens. The fibers of the sympathetic group are carried regularly in the third, fourth and fifth lumbar roots. These fibers pass through the sympathetic chain by a varying number of strands to the inferior mesenteric ganglion, and from this ganglion the hypogastric nerves arise.

The hypogastric nerves carry the impulse to the hypogastric plexus, which is formed by a union of the hypogastric nerves with branches of the nervus erigens.

From the hypogastric plexus terminal branches are distributed to the bladder.

It has been thought by certain observers that they had demonstrated vesicomotor fiber in the sympathetic other than those carried by the hypogastric nerves.

Stewart,[5] however, was unable to confirm their findings, in that when he sectioned the hypogastric nerves, leaving only the sacral paths open, and then subsequently cut the sacrospinal nerves, stimulation of the cord in every instance failed to produce bladder contraction.

The course of the sensory nerves has been somewhat more difficult to determine, inasmuch as stimulation of almost any sensory nerve of the body will produce a reflex contraction of the bladder.

Certain points, however, have been well established. It is definite that the sacral nerves contain sensory fibers from the bladder, which, when stimulated, produce a reflex through the cord and the sacral nerves.

These sacral nerve sensory fibers are part of an arc which is limited to the sacral nerve-cord reflex, inasmuch as they are not capable of exciting a reflex contraction of the bladder through the hypogastric nerves.

It has also been shown that the hypogastric nerves contain bladder sensory nerves. These fibers when stimulated produce a reflex contraction of the bladder, but this reflex is through the inferior mesenteric ganglion, for it takes place even though the ganglion be entirely isolated from the cord. This reflex, however, has been considered by Langley a pseudoreflex or axon reflex.

Griffiths[6] has described a third reflex occurring through the ganglion cells of the hypogastric plexus, and lastly, as pointed out above, some have maintained the existence of intravesical centers which functionate in spite of the isolation of the bladder from its spinal and sympathetic connections.

The exact function of the hypogastric nerves and of the sacral nerves is in doubt.

Von Zeissl,[7] from his investigations, concludes that the bladder conforms to the law of crossed innervation. The nervus erigens is motor for the body and inhibitory for the sphincter, while the hypogastric nerves are motor for the sphincter and inhibitory for the body, or as Strominger[8] puts it, the lumbar center retains the urine while the sacral center expels it. This view is not conformed to by all observers; thus, Louget considers that the sacral nerves control the sphincter while the sympathetic nerves control the body.

Langley and Anderson[9] and Stewart[10] consider that stimulation of the hypogastric nerves differs only in degree from stimulation of the sacral nerves.

Langley[11] has more recently demonstrated the presence of inhibitory fibers in the sacral nerves.

Although stimulation of the hypogastric nerves will often produce contraction of the bladder, usually followed by a much greater dilatation, and stimulation of the sacral nerves usually produces a contraction of the bladder, stimulation of either nerve or of the cord will often produce a dilatation of a previously contracted bladder.

Two views have been held as to the manner in which the sensory nerves are stimulated to give a conscious sensation of the desire to urinate. According to Goltz[12] the distention of the bladder finally calls forth a reflex contraction which squeezes a few drops of urine into the posterior urethra, and the sensation of the desire to urinate arises from the stimulation of sensory nerves of the posterior urethra. A second theory is that the desire to urinate arises from stimulation of sensory nerves of the bladder itself from distention with urine. In support of Goltz's view has been set forth the fact that instrumental or chemical or inflammatory stimulation of the posterior urethra causes a desire to urinate. The fact, however, that this sensation may be thus produced is by no means proof that normally the desire to urinate arises from stimulation of nerves of the posterior urethra. This is perhaps a provision for the complete emptying of the urethra. Against Goltz's view and in favor of the view that the desire to urinate arises from stimulating of the sensory nerves of the bladder itself, is an overwhelming amount of evidence.

Thomson Walker[13] in observations on cases in which the whole posterior urethra had been removed by suprapubic prostatectomy found that there was no difference in these cases in the sensation of desire to urinate and concludes that the prostatic urethra is not concerned in, or is not necessary for, the initiation of natural urination. It might also be pointed out that in many cases after prostatectomy the posterior urethra becomes a part of the bladder and thus is almost constantly full of urine, and yet it is only when the bladder has reached a certain distention that the patient has a desire to urinate. This desire, so far as I have been able to make out, does not differ in any way from the normal sensation.

Mosso and Pellacani,[14] from experiments on women in measuring the volume of the bladder, came to the conclusion that the sensation of fulness and desire to urinate was caused by stimulation of the sensory nerves of the bladder.

Leedham-Green,[15] from roentgenograms of the bladder, failed to find evidence of the opaque medium in the posterior urethra.

It would seem, then, that Goltz's view is no longer tenable, and that the sensation of fulness of the bladder and the sensation of desire to urinate arises solely from stimulation of sensory nerves of the bladder itself and does not come about under normal conditions from stimulation of the nerves from the posterior urethra, although it is evident that stimulation of the posterior urethra does give the sensation of urinary pressure.

The question of the origin of the desire to urinate is closely allied with the function of the sphincter muscles of the bladder.

Henle, from his observations that fibers of the detrusor muscle were inserted between those of the internal sphincter, supposed that the internal sphincter was pulled open by a contraction of the detrusor muscle.

Zuckerkandl[16] has shown that most of the fibers of the detrusor muscle are inserted not between the fibers of the internal sphincter but are attached to the upper part of the prostate. Here, too, the internal sphincter would be regarded as a passive sphincter, as was regarded by Rosenthal[17] as far back as 1857, a view which has no support today.

As will be shown later, there can be no doubt that the external sphincter is capable of retaining urine in the bladder, not by an intrinsic elasticity, but by a tonic contraction, which is capable of being inhibited. There is no reason, therefore, to assume that the internal sphincter cannot and does not maintain bladder closure by tonic contraction.

The question of the function of the internal sphincter and of the sphincter urethrae has long been a debated one.

Guyon[18] and Finger[19] considered that the internal sphincter is too weak a muscle to play a great part at least in retaining urine in the bladder. They considered that when a moderate distention of the bladder had been reached, the internal sphincter is overcome and that a bladder neck is formed so that the prostatic urethra becomes part of the bladder cavity. Under moderate distention, then, the bladder is, according to this view, closed by the internal sphincter, but when fully distended the compressor urethrae muscle maintains bladder closure.

This view, then, necessarily maintains the existence of the formation of a bladder neck in a fully distended bladder; and Finger attempted to prove that such was the case by passing a catheter and noting the distance to which it had been introduced before urine began to flow. When the bladder was moderately full, but the patient had no desire to urinate, it was necessary to pass the catheter from 1 to 1.5 cm. farther than when the bladder was fully distended, and there was a marked desire to urinate; but as Leedham-Green[20] points out, if the posterior urethra had become a part of the bladder the difference should not be so slight, but should amount to the length of the entire posterior urethra or about 4 cm.

Volcker and Lichtenberg,[21] by filling the bladder with collargol, demonstrated that the internal vesical sphincter is the sphincter that prevents the escape of fluid from the fully distended bladder. They never observed the formation of a bladder neck.

To determine this point Leedham-Green injected the bladder of men and youths with a suspension of bismuth and then roentgenographed the pelvis. The observer states, "In every case, I found that whether the bladder was fully distended or not the outline of the organ was oval and not pear shaped, and the urethra was sharply cut off from the bladder without a suggestion of a bladder neck."

Barringer and MacKee,[22] Uhl and MacKinney,[23] and A. Hyman,[24] using practically the same method of filling the bladder with an opaque medium, have all reached the same conclusion, that under normal conditions the internal vesical sphincter maintains bladder closure, and without exception they have failed to demonstrate the formation of a bladder neck.

Physiologists have been somewhat loath to accept the view that the internal sphincter maintains bladder closure, as it would seem to present an example of volitional control of unstriped muscle. There is, however, an example of this in the accommodation muscle of the eye, and the striking example of volitional control of unstriped muscle has been reported by Maxwell[25] in which a young man had the power of voluntary erection of the hair. Another explanation has been offered for the apparent volitional control of unstriped muscle and that is, that it is a reflex voluntarily initiated.

Rehfisch,[26] to prove that the internal sphincter muscle is capable of voluntary contraction, filled a man's bladder and then introduced a catheter so that its opening lay in the posterior urethra through the external sphincter muscle. The man could discharge and retain his urine at request.

From my own observation on cases in which I have performed Young's perineal prostatectomy I am convinced that not only is the internal sphincter muscle capable of maintaining bladder closure independently of the external sphincter muscle, but that it is to all intents and purposes under volitional control.

I am also convinced that the external sphincter muscle can maintain bladder closure independently of the internal sphincter muscle and do so in a reflex manner. This operation provides wonderful opportunity for determining just this point, inasmuch as the opening for drainage from the urethra is between the internal sphincter muscle and compressor urethrae muscle.

In this operation a small slit-like incision is made in the membranous urethra after the compressor urethrae muscle, triangular ligament and transverse perineal muscles have been retracted forward. Enucleation is then carried out subvesically. We have then an opening in the urethra between the external and internal sphincter muscles with, in many cases, a perfectly intact vesical neck.

It is not at all uncommon to see the internal sphincter muscle within a few days regain its function and the patient retain urine in the bladder and volitionally expel it from the perineal wound. It is also possible for him to close the bladder after part of the urine has been passed.

It is evident that in these cases the bladder closure is carried out entirely by the internal sphincter muscle and that this muscle will act volitionally. In further support of the theory that the internal muscle is capable of maintaining bladder closure and is under volitional control, is the fact that incontinence of urine very rarely follows external urethrotomy for stricture with section or destruction of the external sphincter muscle, and the cases in which it does follow might be explained by destruction of the internal sphincter muscle by long distention with urine.

A question of very great importance to the genito-urinary surgeon is whether the compressor urethrae muscle can act in a reflex manner and maintain closure of the bladder independently of the internal sphincter muscle.

As has been shown by Zuckerkandl in cases of prostatic enlargement, due to adenomatous growths, the internal sphincter muscle is sometimes enormously dilated by the growing of the adenoma through it.

Thomson Walker[27] was perhaps, the first to point out that in many cases the internal sphincter muscle is destroyed or rendered permanently useless by this distention. He noted that in necropsy on patients dying after prostatectomy there was frequently a large cavity of bladder neck remaining.

Hyman,[28] and Wallace and Page,[29] by making roentgenographic pictures of the bladder after prostatectomy, conclusively demonstrate that in many cases the internal sphincter muscle is not only functionally useless, but that the posterior urethra forms a bladder neck and that closure of the bladder is at the point of the compressor urethrae muscle.

Again, observations which I have carried out on cases following Young's perineal prostatectomy seem to definitely establish this point. In some of the cases in which a large adenoma has been removed, urine is frequently passed through the perineal wound without interruption until this wound closes, when the patient has perfect control of urination. It might be assumed that, in the cases of enlarged prostate, the external sphincter muscle had assumed a function which it does not normally possess, that with destruction of the internal sphincter muscle and a disturbance of its function by the growth of adenoma throughout it, the external sphincter muscle had gradually taken on itself a reflex ability to maintain constant bladder closure.

I believe that this possibility can be definitely ruled out and that the following clinical observation is of interest in this connection.

A patient, aged 83, consulted me on account of not being able to urinate, and having to use a catheter. Examination showed a small fibrous prostate and cystoscopic examination showed a well-defined posterior bar. A Young's perineal prostatectomy was done and after removing the fibrous prostatic tissue I found that there was an extremely contracted vesical neck, which I dilated with glove stretchers. Five days later it was found that the obstruction had not been relieved and that the patient had retention of urine. I immediately did a Young's punch operation, introducing the instrument through the perineal wound. The vesical neck was freely divided. Following this, urine

drained without interruption through the perineal wound for about three weeks, when a catheter was passed into the bladder through the urethra, and the perineal wound closed that day. Two days later the catheter was removed and urination was found to be normal in every respect as had been expected. It is evident that in this case there was what might be called an internal sphincter incontinence, but that when the perineal wound closed the external sphincter was brought into play, giving the patient perfect urinary control.

It is to be noted also that the external sphincter muscle assumed this control without having to be educated to new conditions. In this connection it is also worthy of note that in a large number of cases in which Young has performed his punch operation, not a single case of incontinence of urine, for even the shortest time, has followed.

Chetwood's galvanocautery operation for stricture of the vesical neck has occasionally, in some hands, resulted in incontinence of urine. This is no fault of the operation itself, in so far as dividing the internal vesical sphincter is concerned, but undoubtedly has resulted from division of the compressor urethrae muscle when incising in the perineum on a sound in the urethra for the purpose of introducing the galvanocautery.

It is believed that if the instrument was introduced as Young's tractor is introduced after the triangular ligament had been retracted forward, incontinence of urine would never follow.

From roentgenograms and from observations on operative cases in which the external sphincter muscle has been excluded, there can be but little doubt that the normal internal sphincter muscle is thoroughly capable of maintaining bladder closure and that to all intents and purposes it is under volitional control. It is also certain that the external sphincter muscle (compressor urethrae muscle) is alone capable of maintaining bladder closure and of acting in a reflex manner.

It would not seem that the subject had been covered without saying something in regard to incontinence of urine following prostatectomy.

The operation of median perineal prostatectomy entirely disregards the physiology of the mechanism of urination and it does not seem remarkable that many cases of incontinence of urine have followed prostatectomy by this method. The only thing that prevents incontinence of urine following this operation is that by chance the internal sphincter muscle might regain its function following the removal of an enlarged prostate through it; or that, by chance, the external sphincter muscle might heal and be restored to function. This operation must not be confused with Young's perineal prostatectomy, an operation after which incontinence of urine should never follow, inasmuch as not only is the internal sphincter muscle preserved for whatever value it may possess, after having been distended by the prostatic adenoma, but that by going in between the transversus perinei muscles and the levator ani, retracting the triangular ligament forward, the external sphincter muscle is preserved.

In one of Young's early series of 540 perineal prostatectomies, he had three cases of incontinence of urine, and frankly states that two of these were due to getting in anterior to the triangular ligament.

In conclusion it might be said:

1. The bladder center is situated in the conus terminalis of the spinal cord.
2. The so-called sympathetic centers are incapable of carrying on, in anything like a normal manner, the mechanism of urination.
3. The desire to urinate arises from stimulation of the sensory nerves of the bladder and not from stimulation of the sensory nerves of the posterior urethra.
4. The internal sphincter muscle normally maintains bladder closure.
5. Although the internal sphincter muscle is plain muscle it is to all purposes under volitional control.
6. The external sphincter muscle is capable of maintaining bladder closure and does not have to be educated to perform this task.
7. Either the external or internal sphincter muscle can, if necessary, be destroyed without interfering with the function of retention of urine, *providing the remaining muscle is in a normal condition.*
8. Median perineal prostatectomy, inasmuch as in this operation the external sphincter muscle is divided and the internal sphincter muscle is liable to be rendered useless by the prostatic growth, is likely to result in incontinence of urine.

Incontinence of urine does not follow Young's perineal prostatectomy, in that in this operation the external sphincter muscle is preserved.

400-401 Marsh-Strong Building.

ABSTRACT OF DISCUSSION

Dr. Martin Krotoszyner, San Francisco: Dr. Cecil's paper calls to mind the not very rare occurrence of urinary disturbances that are apparently located in the prostatic urethra, but which in reality are due to some lesion of the urinary center in the lumbar spine. These cases are characterized by difficulties of micturition simulating involvement of the prostate gland, and, as a rule, also demonstrate cystoscopic changes, like trabeculosis, generally seen in prostatism.

Dr. Frank Hinman, San Francisco: The contribution of Dr. Cecil is important from a surgical standpoint, as it emphasizes the interrelationship of the two sphincters. It is important, before an external urethrotomy, for instance, to know that the internal sphincter is intact, and one would, therefore, hesitate to perform an external urethrotomy on one who had previously had his prostate removed. I can testify to the conservative character of Young's perineal operation in an experience of twenty cases without one death or one case of complete incontinence. In several of these cases the internal sphincter was unquestionably inactive, so that continence was due to the preservation of the external sphincter. Incontinence is of two kinds, false and true. False incontinence has been attributed to inaction of the internal sphincter in which the posterior urethra becomes a part of the bladder. The incontinence expresses itself in an imperative desire to void without the ability apparently of waiting when this desire comes. True incontinence is a condition in which both sphincters are inactive.

Dr. Granville MacGowan, Los Angeles: I wish to say that I have never seen any incontinence of urine following a properly performed suprapubic prostatectomy. I have seen a number of cases following Young's operation, when not performed in a proper manner. This is a thoroughly scientific operation, but one which the ordinary surgeon is incapable of performing. That is the reason why so many cases of incontinence of urine follow the operation.

Dr. A. B. Cecil, Los Angeles: In looking over the literature for the last four or five years on the question of urinary control, I found that the whole physiology of the mechanism of urination was considered more or less a mystery, that incontinence of urine was something that might or might not happen following prostatectomy, and that when it did there was no explanation for it.

I wondered why it was that some operators had reported numerous cases of incontinence of urine following perineal prostatectomy, because I really never have seen but one case of incontinence of urine following Young's operation. The whole reason of this discrepancy was because the mechanism of urination was by some operators disregarded. If one carries out the procedure as advised by Alexander to divide freely the external sphincter muscle, we would surely expect to get a certain number of cases of incontinence of urine. From the very first Dr. Young in perineal prostatectomy preserved that muscle, and if we preserve the external sphincter muscle in these operations, incontinence of urine will not follow. There is no mystery about it.

DIAGNOSES AND CERTIFICATES OF DEATH

WITH ESPECIAL REFERENCE TO CANCER*

JOSEPH S. LEWIS, M.D.
BUFFALO

The life of a health officer is often spared by certain phases of human frailty with a humorous side. Among the complaints which come over the wire to the health department of Buffalo are such as these: "My husband is a pest and I want him removed." (A nuisance, evidently, to be abated.) "I want someone to do my washing, I can't get around to it." "Please send someone to kill off the cockroaches in my house. They are so thick that yesterday they stopped the clock." Such breezes serve to cool the fevered brow of the registrar of vital statistics while he wrestles with the problem of translating death certificates into figures qualifying and summarizing human mortality. When the registrar finds "asthenia," "neurasthenia," "Christian Science" or "climacteric," seriously certified as cause of death and ventures a mild protest, he is usually bidden to write a better one if he knows of one. How vital are vital statistics need not be urged here at length. Let any skeptical practitioner simply ask himself what would become of the science of preventive medicine without the knowledge of the whereabouts and extent of preventable disease, and the answer must solve his doubt as well as remind him of an important duty toward humanity. The importance of studying this question of the correctness of statistical diagnosis is less aid to the clinician who carries through his case conscientiously than for the sake of vital statistics. You may name a condition anything, or as many things as you please at the bedside, provided you treat your patient wisely, but for the Bureau of Census the diagnosis can be but one thing, and that as near as careful reflection can arrive at the truth. Nevertheless a preeminent clinician may be so far from connecting cause with effect as to quote with assurance death rates weakened by his own carelessness or impatience in writing out a death certificate.

For some time, in pursuit of the reason for the real or phantom increase in the death rate for cancer, I have been increasingly impressed with the importance of the question, "What of the diagnosis?" Death rates by cause depend largely for their accuracy on the accuracy of the individual physician both in determining and in recording the cause of death. It follows that the figures are certain when the physician is certain, and contrariwise.

In certain causes of death, doubt as to relative frequency is within limits so narrow as to be negligible, for example, in all deaths due to violence. Next to violence come the contagious diseases like smallpox, whooping cough or scarlet fever. Their universally recognizable signs and symptoms and their contagious nature make their diagnosis and reporting practically certain. All deaths followed by necropsy are likewise accurately reported, but in the absence of universally performed necropsy are of value only in proportion to their number. The value of such accurate data alone more than compensates for the labor and expense of gathering all. Of most doubtful value is the summary of causes that arise from conditions that remain hidden within the body cavities without clinical laboratory confirmation or necropsy. The sources of error which tend to vitiate accuracy in the latter class of certificates are many. The important ones are obscurity of the disease, lack of time and opportunity for study of its course, the lack of acumen of the physician, his unwillingness to take pains with the death certificate, and finally the interpretation by the registrar of the physician's interpretation of the signs and symptoms. The literature on the subject of diagnosis, as such, is scanty. How often is the diagnosis right? Do mistakes of omission and commission counterbalance and give approximately correct results, or are the figures subject to false inflation and deflation as the result of fads or educational propaganda?

Cabot[1] made a serious attempt to contribute something on this theme. From the printed discussion of his paper we deduce perfunctory commendation by some who heard the paper and a sweeping denunciation of the work, by Dr. A. C. Croftan of Chicago in subsequent letters to The Journal. Dr. Cabot's statements have received further confirmation in a report out of Bellevue Hospital.[2] Ash[3] contributes data concerning mistaken diagnoses in tuberculosis, and Bissell and LeCount[4] have discussed the diagnosis of coma. Greenwood and Wood[5] also present a significant discussion concerning the mortality from cancer. As physicians it is one of our most common weaknesses, arising from the patient's abhorrence of perplexity, that we fear to face our own diagnoses save in the dark. With a necropsy in prospect, few of us care to commit ourselves to a concise cause of death as we inevitably must, on a death certificate.

It was with the hope of throwing some light on this subject that I undertook a perusal of all death certificates issued in Buffalo for the year 1914, and by way of comparison, for the year 1894. It was a tedious work though punctuated with lighter moments as previously mentioned. A word as to the average physician's average opportunity (reference to ability is studiously avoided) to make use of all the helps that modern medicine has to offer, will not be out of place. In 1914, in Buffalo, an average American city, of about half a million inhabitants, the deaths were about seven thousand. The births for the same year were about twelve thousand. Now of these twelve thousand births, five thousand were attended by midwives. These five thousand midwifery cases called for at least five thousand out of twelve thousand families in which medical practice in serious cases is conducted under the following regulations. First, no physician to be called until the patient can bear it no longer, usually at night; second, the physician is not to come again until called for; third, the physician's pay is inadequate so that he must in such cases make too many calls a day, to give each case attention that will stand scientific criticism. In 1914, some four hundred certificates were made by the medical examiner or city diagnostician on evidence obtained after death without necropsy in nontraumatic cases in which criminality was not suspected. I think it fair to assume that most deaths certified to under such circumstances render diagnoses so subject to error as to be mere guesswork. The large majority of these deaths were, for adults, some disease of the heart or blood vessels, for infants, malnutrition or convulsions. I am of the opinion that guessing is by no means confined to the above kinds of certificates, but accompanies other sources of error mentioned above and now to be considered. Table 1 gives the gross results of the examination of death certificates at their face value, comparing the year 1914 with the year 1894, to show what progress, if any, has been made.

TABLE 1.—PROGRESS SHOWN IN BETTER PREPARATION OF DEATH REPORTS IN 1914 AS COMPARED WITH 1894

	Total Deaths	Given Cause Doubtful	Improperly Arranged or Worded	Conflict of Two or More Given Causes
1894	5,280	501	274	170
1914	7,040	277	639	480

TABLE 2.—CONTRADICTIONS NOTED IN VARIOUS DEATH CERTIFICATES

Cause	Contributory Condition	Comment
Uremic poisoning (duration twenty days)	Albuminuria (duration three days)	
Pernicious *anemia* (duration, three months) laborer, 43 yrs. old	....	Physician attended one day
Dilatation of heart (duration, one year)	....	*Physician* attended *one* day
Acute yellow atrophy (adult)	....	Duration seven months
Acute nephritis	....	Duration one year
Chronic endocarditis...	....	Duration *fifteen* years
Gastro-enteric catarrh (duration two mos.)	Influenza (duration fifteen days)	Woman, aged 22
Graves' disease	Ptomain poisoning and valvular heart disease	Believe contributory, here were signs of cause
Asthma of lungs......	Laborious work	Emphysema?
Chronic bronchitis (duration one year)	Pulmonary hemorrhage	Tuberculosis?
Hypertrophic cirrhosis of the liver (man aged 56)	Valvular heart disease, mitral (duration one year)	Chronic passive con*gestion?*

Consideration in detail of the headings, with examples given, will make clear the kind of certification it is intended to criticize or question. Table 2 shows examples from certificates (year 1914) containing various contradictions. Duration is inconsistent with disease or patient with disease, and in some few cases I know that the cause of death as stated was probably incorrect. Statements not essential to the point are omitted.

Examples of certificates improperly made out, for example, with transposed or conflicting causes or with a multiplicity of nonessential causes are given in Table 3. Remember that the registrar can send to the census but one cause of death per death, and consider these causes. Some of these examples come from the best equipped men in the city and from hospitals. They were transcribed without alteration.

TABLE 3.—EXAMPLES OF IMPROPERLY GIVEN CAUSES OF DEATH

Primary or Statistical Cause	Contributory Conditions
Aortic stenosis, aortic insufficiency, mitral stenosis, nephritis, ulcerative colon.	Cardiac dilatation, uremia.
Bronchopneumonia. heart disease — mitral, progressive muscular atrophy.	*Hemiplegia.*
Acute appendicitis, appendix abscess, subperitoneal abscess, volvulus.	Plastic peritonitis, acute suppurative peritonitis.
Alcohol poisoning and heart failure from *overstimulation from alcohol. Patient* had been drinking very heavily for last three weeks.	When not under alcohol patient was in good health.

A common practice is to transpose, that is, give the contributory condition for the primary cause of death, and vice versa. This error does not affect a diagnosis which in itself may be correct, but if, for instance, an adequate contributory condition is put down in place of an adequate primary cause and the two causes contributory and primary are transposed, the registrar may be justified in reporting for the census a contributory cause which is in fact erroneous. Many physicians are not yet clear on what is a primary and what a contributory cause. This is not always easy to state, but granted the distinction can be made, the primary is the statistical cause of death, namely, that which goes through to the census reports. With this in mind the diagnostician cannot write "starvation" in the space where "cancer of the esophagus" ought to be.

Words added to certificates which serve no useful purpose but only confuse are the usual terms deprecated in the physician's pocket reference of the international list of causes of death, such as: marasmus, exhaustion, asthenia, cachexia, inanition, general weakness, dentition, and so on. They usually signify uncertainty. Those certificates, otherwise correct, which use these terms of infants especially in prematurity, have not been considered, as they appear so frequently.

TABLE 4.—EXAMPLES OF TRANSPOSITION

Cause	Contributory Condition
Inanition-myocarditis	Cancer of the esophagus
Toxemia	Pulmonary tuberculosis
Edema of lungs	Cerebral syphilis
Bronchial pneumonia	Pertussis
Brain pressure	Cerebellar tumor

Examples of conflicting diagnoses may be given. When two or more separate adequate causes of death occur simultaneously in the same patient, as said before, only one may be chosen by the registrar. The insane asylums, for example, are a fruitful source of such conflict, for in most cases where insane patients die of a well-marked psychosis other important causes give way. The following examples were all taken from certificates.

Tuberculosis
Dementia praecox

Epilepsy
Nephritis

Scarlatina
Diphtheria

Cancer
General paresis

Nephritis
Diabetes
Syphilis

Intestinal obstruction
Pertussis

The overshadowing disease, usually that of longest duration, becomes the cause of death. The difficulty presents itself peculiarly well in the coincidence of intestinal obstruction and pertussis. Intestinal obstruction in this case considered clinically would, as the predominating cause of death, take precedence over pertussis. Statistically, however, it is vastly more important to the community to know that there has been another death from pertussis, and the case would probably be so recorded.

Now take the year 1894. Under doubtful causes, be it noted that many more certificates were doubted than in 1914, in the first place because certificates were accepted then that would now be sent back for correction. In most returned and corrected certificates of 1914 there is reason to presume that the diagnosis was not thereby rendered more correct, but simply more in outward conformity with the international list of causes. On the other hand, many oft-repeated diagnoses of 1894 reflect by contrast the advance in medical knowledge during twenty years. Typhoid pneumonia was still a common expression, usually meaning a rapidly fatal pneumonia accompanied by a condition of shock. Various "congestions" of brain, liver, lung, etc., were still in vogue. "Membranous croup" was accepted, though it was grouped with diphtheria in the final accounting; similarly "enteric fever" with typhoid. Some typical examples of doubtful diagnoses, written in 1894, may be noted.

TABLE 5.—EXAMPLES OF DOUBTFUL DIAGNOSES

Cause	Contributory Condition	Remarks
Typhoid fever (woman, aged 79)	....	Duration seven days
Typhoid fever (child, aged 5)	....	Duration two days
Apoplectic stroke......	Abscess of brain.....	Child 3 years old
Neuralgia of heart....	....	Child 6 years old
Chlorosis	....	Negress, aged 19
Severe nervous deviation due to changes of puberty	....	Girl, aged 14

An interesting example is the following diagnosis after necropsy in which the cause would today doubtless have been ascribed to a stone in the ampulla of Vater.

Cause	Contributory Condition	Remarks
Hepatitis, perihepatitis, cholecystitis, enteritis (small intestine) (localized peritonitis), pancreatitis, pancreatic hemorrhage	Gastralgia and vomiting, collapse from shock	Woman, aged 62. Necropsy performed

There were instances in both years when the physician expressed on the certificate doubt of his own diagnosis. And yet, perforce, no such doubt was expressed in the census unless the case was classified among the "doubtful causes," which was not done unless the cause given was in itself doubtful. As may be supposed, the average faulty diagnoses were much more obviously and frequently incorrect in 1894 than in 1914. Conflicting causes, on the other hand, were far less frequent in 1894. The reason for this is to be found in an off-hand certainty which pervaded these earlier documents. Usually no duration was given. A physician took his duty much more lightly and the certificates were generally made out with far less care. As to improper certificates, the great increase in their number in 1914 was due to the overanxiety to be correct. The certifying physician nowadays feels that one cause may not stand alone, it must be plentifully characterized and fortified with contributory features which would make the dénouement appear inevitable, in order to avoid any dispute with the registrar. It is now, therefore, more often than ever the task of the registrar to choose from a number of causes that which seems the most likely.

Now taking only such as show striking differences, let us compare some given diseases in frequency of diagnosis. This with the idea of gaining an impression, more cannot be proved, whether diagnosis is in all things vastly better or whether it is so of certain diseases only while other increases or losses come of insistence that the certificate shall look more truthful whether it be so or not.

TABLE 6.—INCREASED OCCURRENCE OF DISEASE AS SHOWN IN DIAGNOSIS

Syphilis	1894	1914
Adult	12	32
Congenital	14	88
Congenital (subdivided)		
In X, infant asylum..........	1	54
In rest of city..................	13	34

In Table 6 the first and last line of figures might represent the normal increase proportionate to population. The second and third lines, however, show an enormous increase, and this is found to be due to a great number of diagnoses coming from one institution, probably indicating better diagnoses in that institution, whereas much infantile syphilis occurring elsewhere is lost under other headings.

Table 7 indicates a striking increase in a more definite as against a sharp decrease in a less definite diagnosis of the same character. This change is presumably one of the effects of insistence on more definite terminology.

TABLE 7.—INCREASE DUE TO MORE DEFINITE DIAGNOSES

	1894	1914
Apoplexy	112	216
Paralyses (not paresis)...............	57	21

A search was made for instances of an increase, due with the least possible doubt to improved knowledge. The first column in Table 8 gives the actual number of certified deaths of 1894 due to the disease chosen, then the number of cases interpreted from certificates of the same year as probably due to the disease, but otherwise stated. In the last column are the official totals for 1914. The "possibles" for 1914 were insignificant in number.

Note in Table 8 that in 1 and 2 the first two figures added give an approximately normal increase. In 3 the excess increase may be partly accounted for by postoperative deaths. In 4 the signs could not be read into a death certificate, being dependent on a blood count.

TABLE 8.—INCREASE DUE TO IMPROVED DIAGNOSES

	1894 Actual	1894 Possible	1914
1. Appendicitis	15	25	77
2. Prostatic disease (not cancer)	4	11	22
3. Exophthalmic goiter	0	2	17
4. Leukemia	2	0	13

Table 9 gives a comparison showing changes due in part to suppression of the really justifiable diagnosis of "old age." This term may be a refuge of ignorance or one under which to group the aged dead when time or opportunity is lacking to make out more definitely the terminal disease. Many physicians who would formerly have written "old age," "heart failure," "gastritis," "exhaustion," "dropsy," or what not, will now write arteriosclerosis, myocarditis, or nephritis, either together or separately and probably in many cases by reason of circumstances previously enumerated get no nearer the truth.

Table 10 shows that the disproportionate increase in violent deaths was due to insistence on supervision by a medical examiner in all cases in which there was history of trauma leading to the terminal illness, whether or not death was the immediate outcome.

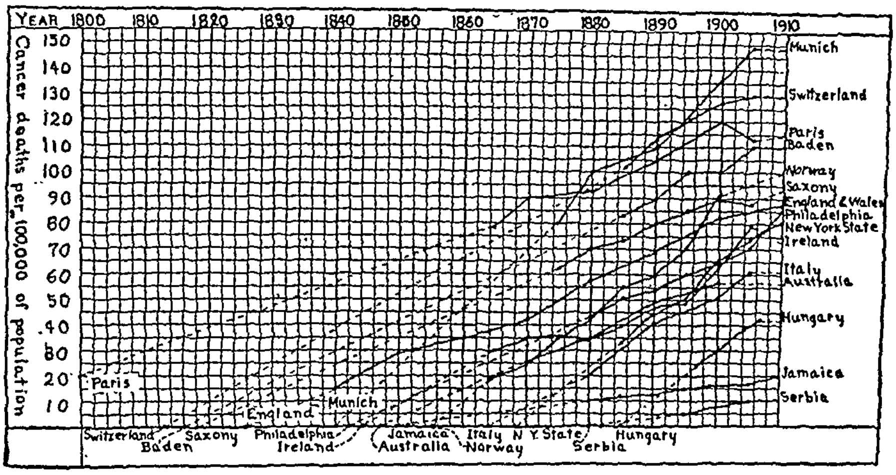

Fig. 1.—Cancer deaths per hundred thousand of population.

The diagnosis, chronic nephritis, as indicated in Table 11, is increased not alone by any marked change in prevalence of the disease, but partly by the fact that in a certain number of old people it constituted the "last straw" or terminal breakdown. To mix such deaths with those of children or adults taken out of vigorous life by Bright's disease is confusion. In the case of senile persons with a late nephritis, it had better have been set down that they died of senility than to have added the terminal disabling of any given organ to the category of important causes of death. Hence, to compare today's death rate for chronic nephritis with that of twenty years ago, without due regard for change in the character of certification, is fatuous.

TABLE 9.—COMPARISON SHOWING DROP IN REPORTED CAUSE OF DEATH AS DUE TO "OLD AGE"

	1894	1914
Arteriosclerosis	1	392
Old age	189	44

It is therefore incorrect to expect from the decrease in the diagnosis "old age" the chief source for the increase in cancer.

A similar source of error exists at the other extreme of life. As in senility old age is the important factor, so here it is infancy itself. From the clinician's point of view it was all important that the dead infant was fed on pickles and coffee. From the statistician's point of view the important factor was the infancy, because later in life pickles and coffee have little or no particular etiologic significance. Wherefore infantile malnutrition and *malassimilation*, as the case may be, should have just the same repute in a statistical diagnosis as senility. In such cases the clinician should not be made to feel forced, in the face of a clinical uncertainty, to find a point in the respiratory, circulatory or gastro-intestinal tract on which to hang his diagnosis. For these reasons the mortality figures of forms of death common in infancy, save still birth and the contagious diseases, are of little value in establishing the death rate for any given disease.

TABLE 10.—INFLUENCE ON REPORTS OF SUPERVISION BY MEDICAL EXAMINER

	1894	1914
Certificates made by official diagnostician or medical examiner	140	1,111
Total violence	240	444
Trauma due to fall	18	100

Now to my main purpose, namely, to consider the cancer diagnosis as a diagnosis, and how it may be affected by factors other than the true or actual death rate for cancer. To begin with, there is no doubt that, whatever the cause, the cancer death rate curve shows throughout the world a steadfast and rapid rise unlike that due to any other cause, save, in a minor degree, diabetes. Figure 1 will show this graphically. This chart will also indicate certain startling conclusions.

If the death curves run upward at the present rate, in a short time, say another generation, cancer will far outstrip other causes of death in persons of the cancer age. That this forecast is fallacious can be demonstrated with equal propriety by reversing the process, running the curve backward, as is done in the chart

TABLE 11.—APPARENT INCREASE IN DEATHS FROM NEPHRITIS AND DISEASES OF CIRCULATORY SYSTEM

	1894	1914
Arteriosclerosis	1	392
Myocarditis, fatty heart and cardiac paralysis (*in persons over 60*)	30	*
Nephritis, chronic (in persons over 60)	45	250
Total circulatory	344	1,117

* Now included under organic diseases of heart.

by means of dotted lines. The cast backward at the same average rate will seem to show that previous to 1800 there was practically no cancer worthy of mention anywhere on earth, and that our own state of New York had less than 1 cancer death per 100,000 of population previous to 1865. This would give for that year about 40 deaths for the state, due to cancer! The only country showing a sharp deviation from this curiously steady upward slant is Ireland, which difference may be explained by the obvious reason of the unparalleled depletion in a short time of its adult population by emigration. Another striking diagram is that giving four causes of death for the state from 1885 to 1912, inclusive (Fig. 2).

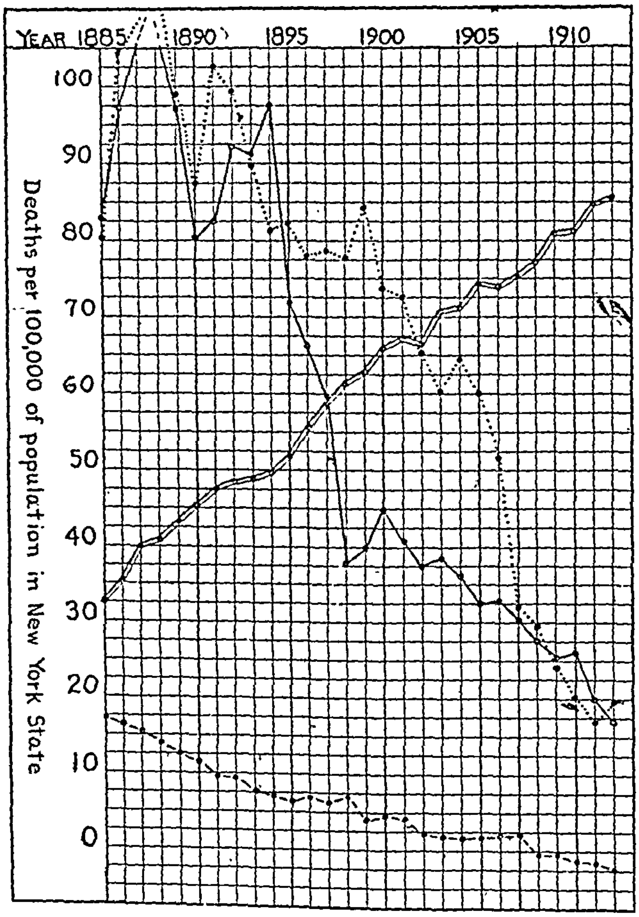

Fig. 2.—Deaths per hundred thousand of population in New York State: double line, cancer; dotted line, old age; solid line, diphtheria; line of dashes, malaria.

"Old age" is a diagnosis which has been during this given period sharply on the decline, not because of any sharp decrease in the relative incidence of old age, but almost wholly because of suppression of the term in the interest of supposedly greater accuracy of statistics.

"Diphtheria" is a diagnosis which has dropped *pari passu* with "old age," for an entirely different reason, namely, because of an actual decline in the number of deaths due to this disease in the face of methods of diagnosis which have shown it to be far more widespread than was formerly supposed. In 1894 there were made in the whole year at Buffalo 147 bacteriologic examinations for diphtheria; in 1914 as many every three days.

Diagnoses of malaria diminished, due both to improvement in diagnosis and in the incidence of the disease, certainly more by the first than by the second reason. In other words, examination of the blood has done more to diminish deaths due to this disease in New York by proving its rarity than has the extermination of the mosquito, though there was undoubtedly more of it in the state at one time than at present. So far as is known it was always the tertian form, a variety not serious in itself and most easily controlled by quinin. Fatal cases that occur in this state nowadays can be only in patients brought up from the tropics to die. Death due to locally acquired malaria belongs to the anomalies and curiosities of medicine.

Cancer is still in doubt.

It is a strange coincidence that the diphtheria and old age curves should be so alike, though produced by such fundamentally different causes. It appears, therefore, that two diseases may seem to diminish in a parallel from wholly different causes. It follows that the increasing curve of cancer may be due to any one or a variety of causes.

In general, cancer, as indicated by malaria, old age and diphtheria, may increase from four causes: (1) forcing the diagnosis to avoid controversy or as result of popular or professional cancer campaigns; (2) improved diagnosis and more frequent disclosure of the disease; (3) actual increase in the incidence of the disease; (4) age and sex constitution, reference to which is omitted as outside of the scope of this article. According to Table 12 let us consider what a comparison of cancer death certificates in Buffalo in 1894 and 1914 might indicate.

The cancer increase is certainly not due to an exchange with old age because, as shown previously, old age has become scattered under various headings, principally arteriosclerosis, organic heart disease, and nephritis. It is probably not due alone to forcing, because a doubtful condition in a person of the cancer age may be given any one of several names conforming with terminal symptoms. The figures, however, appear to countenance the idea that a considerable part of the increase is due to forced diagnosis. This is hinted at by the decided increase over the natural growth of population in the number of doubtful cancer certifi-

TABLE 12.—APPARENT INCREASE IN DEATHS FROM CANCER

	1894		1914	
	Total	Ratio	Total	Ratio
Population	300,000	1.	454,122	1.5
Total deaths	5,280	1.	7,040	1.25
Total cancer deaths	164	1.	428	2.6
External cancer	39	1.	82	2.1
Internal cancer	125	1.	346	2.77
Certified cancer, was probably not	13	1.	36	2.77
Certified something else; was probably cancer	40	1.	58	1.45

cates, that is as 13:36, or 1:2.77, which approximates the increase for internal cancer. Furthermore, certificates not for cancer, but which might on their face value have been cancer (1:1.45) take a place between the increase of population (1:1.5) and that of the total deaths (1:1.25). Examples of certificates giving cancer as cause of death which seemed likely not to have been cancer at all are given in Table 13.

TABLE 13.—EXAMPLES OF POSSIBLE ERRONEOUS DIAGNOSIS OF CANCER

	Cause	Contributory Condition	Remarks
1894	Intestinal cancer, woman aged 38		Duration four yrs. No hint of operation or necropsy*
	Cancer of stomach, man aged 64		Duration one and one-half yrs. No necropsy or operation. Attended for two weeks
1914	Cancer of intestines, boy aged 10		No operation or necropsy noted
	Infection of gallbladder, chronic ulceration of intestines, malignant degeneration head of colon with obstruction	Chronic malarial toxemia dysentery	Man, aged 36. No operation or necropsy recorded

* Death in a hospital was taken as presumptive evidence of a correct diagnosis.

In Table 14 are examples of certificates giving some cause of death not cancer, which it seemed might easily have been cancer.

Improved diagnosis as a factor in the increase is indicated by a markedly greater increase under the head "internal" as opposed to "external" cancer. The dividing line between external and internal cancer was arbitrarily made, by including as external those cancers which might have been discovered by the patient as distinguished from those discoverable as a rule only by complex methods, operations or necropsy. The increase in the population is represented by the figures 1:1.5, the increase in external cancer by the figures 1:2.1, and the increase in internal cancer by the figures 1:2.77.

TABLE 14.—PROBABLE DEATHS FROM CANCER NOT SO REPORTED

	Cause	Contributory Condition	Remarks
1894	Marasmus, malnutrition (duration four months)	Metritis, inflammation of stomach and esophagus	Woman, aged 44
	Inanition	Stricture of pylorus peptic ulcer	Man, aged 50
1914	Influenza, myocardial degeneration and dilation	Stricture of the esophagus, marasmus (two years' duration)	Man, aged 62
	Pernicious anemia (duration six months)	Rectal hemorrhage (duration one month)	Woman, aged 54

Actual increase in cancer, if any, must therefore share the statistical increase with the two other causes of increase. The numerical importance of these two other causes cannot be accurately determined by any such crude methods as the inspection of death certificates, but their influence is indicated not only by the figures quoted before, but also by impressions gathered from their perusal. These impressions cannot be set down in type, as they are derived from acquaintance with the certifying physician, or the death to which he has certified.

The studies of Cabot and others referred to in the beginning indicate substantial errors in general conclusions based on a large increase in cancer. However, they go no further than that we are not justified in taking the figures at their face value, but must allow for a margin of error of from 10 to 90 per cent. according to the difficulty of the case. This paper serves to emphasize that over and above diagnostic differences and errors, the limits of accuracy are still broader and more uncertain when the death certificate, even with due reference to age conditions, is called on to prove anything. These considerations led me to the following conclusions:

1. The majority of all deaths take place under circumstances that make accurate diagnosis improbable or impossible, wherefore death certificates are, in the majority, of doubtful accuracy. The sources of error are of a nature that tends to increase the apparent cancer death rate.

2. Deaths certified as due to (a) contagious or epidemic diseases, (b) violence, (c) causes verified by necropsy or operation, may be set down as the most comprehensive and accurate: all other causes are proportionately subject to inflation or diminution due to influences apart from the actual incidence of a given disease.

3. To give more accurate results within the limitations of error, the final classification of disease for the census should be modified by further study. To separate conclusive from fallacious causes there should be a large place (a) for deaths, of themselves uncertain in character, for example, nonviolent deaths certified by medical examiners without previous observation; (b) for all deaths of infants under 2 years of age and of old persons over 70 years of age in whom infantile debility or senility is a predominant condition; (c) all unknown causes should be frankly certified as unknown, for example, as cerebral, thoracic or abdominal unknown. Certificates of this kind would be naturally diminished in time by improved knowledge and should not be curtailed or abolished by arbitrary insistence on the giving of a "satisfactory" cause.

4. Death rates for disease can be made accurate only by universal necropsy. As a preliminary measure to introduce universal necropsy the law, as regards necropsy, should be made permissive, in order that a necropsy might be performed save when the deceased or nearest relative expressly prohibits it. This measure would tend gradually to break down useless prejudice partly sustained by the present law, which pro-

vides that the nearest of kin shall expressly and in writing consign the deceased to the diagnostic dissecting table. Necropsy should be a privilege of humanity for the living, not a penalty of the notable or notorious dead.[6]

5. If there is anything to be gained by the study of cancer statistics of this country in their present condition as regards cancer increase, it is rather in figures from small well-ordered communities over many years, where the figures may be controlled on the spot, than in taking broadly summarized figures of the general census for cities, counties and states.

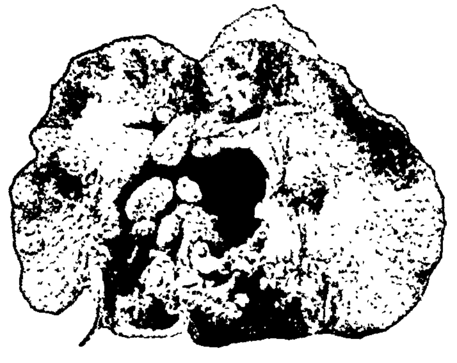
SUPERNUMERARY KIDNEY

HERMAN LOUIS KRETSCHMER, M.D.
Urologist to Presbyterian Hospital; Genito-Urinary Surgeon to Alexian Brothers Hospital
CHICAGO

Cases of true supernumerary kidney may be considered one of the rarest of all pathologic renal conditions. A very interesting and brief reference to this subject was given by Voigtel[1] in 1805. He mentions cases reported by Blassius, Cruveilhier, Dupuytren, Eustachius, Gavard, Hyrtl and Haller. Voigtel, who reported the presence of four kidneys, also mentions a few writers, namely, Bottalus, Dellstang, Gemma and Schenk, who reported the presence of four kidneys.

The occurrence of accessory kidneys is not limited to man. Von Hansemann[2] found an accessory kidney in a pig, and Pieth[3] demonstrated the presence of a third kidney in a cow. This kidney was separate from the two ordinary kidneys, which were normal in position and structure.

Supernumerary kidney must be differentiated from cases of double kidneys. This form of anomaly is also very rare, but it is found more frequently than are cases of accessory kidneys, so that one may consider the latter as being relatively more common than the former. Failure clearly to differentiate between these two conditions is apt to occur when part of the double kidney has undergone some pathologic change. This oversight has occurred in some of the publications in which cases of undoubted double kidney are reported as supernumerary kidney. Suter,[4] in a recent article on this subject, tabulates nineteen cases. Several of these are not above reproach and undoubtedly should be reported as cases of double kidney. It may be questioned whether both of Suter's cases should be considered as true supernumerary kidneys.



Supernumerary kidney which contained thirteen stones. This kidney was not attached to either of the other two kidneys, and had its own blood supply.

I wish to report the following case:

Mrs. W., aged 27, complained of recurring attacks of kidney-stone colic. The present illness began two years ago, at which time the patient had her first seizure. This began very suddenly with a severe pain in the left kidney region, which lasted several hours, and was preceded by a chill and fever. Three weeks later she had another attack, and these have since recurred about every three weeks, usually persisting for a day; one lasted three days. During the first attacks she did not observe the urine, but later, after each attack, the patient always found stones, and the urine was tinged with blood.

During the last month or two, she states, her urine was very turbid. The attacks were always associated with nausea and vomiting. There was some frequency of urination, the patient being obliged to void every two hours during the day, and several times during the night. There was more or less pain and burning on urination. There is no history of previous illnesses. Menstruation is regular, of the twenty-four day type. The bowels show a tendency to constipation since the onset of her illness.

Physical Examination.—The patient is a well-developed, well-nourished woman. The pupils react to light and accommodation. The thyroid gland is enlarged, both lateral lobes and isthmus; there are no symptoms of Graves' disease.

The recti muscles are slightly separated. The left kidney is palpable. Deep pressure over the right kidney causes pain and muscular spasm, the tenderness being more marked posteriorly.

Examination of the thorax was negative as regards heart and lungs. The examination of the extremities was also negative in result.

Cystoscopic Examination.—June 8, 1914: Bladder negative except for the presence of small adherent whitish flakes of mucopus. A small polyp was seen on the internal urethral orifice. Double ureteral catheterization was easy.

URINARY ANALYSIS

Right Kidney

Appearance	Clear
Albumin	Trace
Sugar	0
Microscopic Examination	Negative
Cultures	Sterile

Left Kidney

Appearance	Turbid with flakes of pus
Albumin	+
Sugar	0
Microscopic examination	Pus in large amount
Cultures	Sterile

Result of Phenolsulphonephthalein Test, Intravenous Administration, Thirty Minutes' Collection

	Right Kidney	Left Kidney
First fifteen minutes	17.5 per cent.	11 per cent.
Second 15 minutes	9 per cent.	8 per cent.
	26.5 per cent.	19 per cent.

Total output for thirty minutes, 45.5 per cent.

The blood examination showed leukocytes 7,900; hemoglobin (Dare) 73 per cent.; blood pressure 146.

Roentgen-Ray Examination.—In the region of the left kidney there were seen many more or less indistinct shadows. These shadows were very faint. The roentgenogram did not resemble that usually seen in cases of kidney stone. Because of these peculiar findings a possible diagnosis of incrustations of the renal pelvis was made.

It was decided to perform a pyelotomy and to curet the areas of incrustations and remove any calculi that might be present.

Operation.—June 10, 1914: The usual oblique incision was made. The kidney was exposed without any difficulty but it could not be delivered because of the extremely short pedicle. Numerous stones were palpated in the pelvis. Small depressed scars were seen on the surface. Pyelotomy could not be carried out because it was impossible to bring the kidney up far enough to expose the pelvis. After careful deliberation it was decided to remove the kidney, which was full of stones. The kidney, except that it was small, did not differ in appearance from any other kidney.

[2] Von Hansemann: Berl. klin. Wchnschr., 1897, p. 81.

[3] Pieth: Jahresb. f. Urol., 1909, p. 419.

[4] Suter: Folia urol., August, 1913.

The wound area was thoroughly exposed with retractors before closing and a dark mass was seen in the depths of the wound. I attempted to remove this with my finger, thinking it was a blood cot. This small mass had a pedicle which was clamped, tied and cut. It proved to be a supernumerary kidney, which also was full of stones. This kidney had its own pelvis and its own blood supply. (See illustration.)

Cystoscopic Examination.—July 6, 1914: The bladder still shows a slight degree of cystitis. Both right and left ureters were negative. Only one ureteral orifice was seen on the left side. Examination of the urine still showed the presence of pus. This postoperative cystoscopic examination was made especially to determine whether or not there were three ureteral openings in the bladder.

From a careful study of the recorded cases, it is quite apparent that one of the greatest difficulties arises in making an accurate preoperative diagnosis. Calabrese[5] made a probable preoperative diagnosis of supernumerary kidney in his case, by palpation. Palpation is necessarily of limited value; and a positive diagnosis made from this alone seems to be quite an assumption. The presence of three ureteral orifices in the bladder is only of partial help, as this is not pathognomonic. Three ureteral orifices may be seen cystoscopically in cases of double ureter and double pelvis. As a matter of fact this aid was absent in the cases of Rustschinski,[6] von Hansemann, the case mentioned in the U. S. Marine Hospital reports,[7] Calabrese, Tonkow, and Isaya,[8] in which only two ureteral orifices were found in the bladder, the two ureters of the same side having fused outside of the bladder. This was exactly the condition in my case, the ureter from the accessory kidney fused with the ureter of the normal kidney on the same side, outside the bladder (see postoperative cystoscopy). Barlett[9] reported three ureteral openings in the bladder and Wedensky's[10] case was unique in that the ureter of the accessory kidney terminated in the prostatic urethra. So far as I know this is the only case in which the ureter of a supernumerary kidney so terminated.

It seems as though the diagnosis might be made in suspected cases by means of pyelography. Inasmuch as we know of the tendency of these ureters to unite outside the bladder, the ureteral catheters might be inserted only a few inches into each ureter and then the solution be allowed to find its way into each renal pelvis. The presence of three separate and distinct pelves in the roentgenogram might aid in establishing the diagnosis. (?)

It is perfectly obvious that the shadowgraph catheter would be of doubtful value in establishing a diagnosis in this group of cases.

The rare occurrence of this condition, the scarcity of case reports, and the lack of detail in reporting the cases, leaves much to be desired in our knowledge on this subject.

There was nothing in the history, cystoscopic examination or Roentgen-ray findings in this case to cause us to suspect the presence of this rare anomaly.

Of interest is the fact that, in four cases, this condition was found on the right side (Watson Cheyne,[11] Isaya, Tonkow and Wedensky). In eleven cases the condition was found on the left side (Barlett, Cobb and Giddings,[12] Calabrese, von Hansemann, Hyrtl,[13] Munro and Goddard,[14] Mills,[15] Newman,[16] U. S. Marine Hospital Service Reports, Rustschinski, and my case).

The kidney, in Mills' case, was discovered in the dissecting room. The cases reported by Wedensky, Rustschinski, von Hansemann, Bartlett and Newman are given in necropsy reports. Clinical cases were reported by Cobb and Giddings, Calabrese, Depage,[17] Isaya, Munro and Goddard, and Watson Cheyne.

Many of the cases reported do not contain definite statements regarding the pathologic condition which existed in the supernumerary kidney; the statement is simply made that an accessory kidney was found. My case is the only one in which calculi were reported present. It is, furthermore, the only one in which two of the three kidneys were the seat of the disease.

In Rustschinski's case, all three kidneys were the seat of foci of suppuration, and it is apparently the only case in which all three kidneys were diseased. In the remaining cases the pathologic conditions mentioned as found in the supernumerary kidney were: cystic changes (Wedensky), rudimentary pelvis (Mills), papillary cystadenoma (Cobb and Giddings), movable kidney (Watson Cheyne), pyelonephrosis (Munro and Goddard).

122 South Michigan Boulevard.

ACUTE ASCENDING HEMORRHAGIC MYELITIS *

BENJAMIN T. BURLEY, M.D.
Visiting Neurologist, Memorial Hospital and Worcester City Hospital
WORCESTER, MASS.

The title of this article is descriptive of a rare pathologic condition which has comparatively recently come under my observation. Its rarity is attested by the fact that in the literature very few cases can be discovered of this combination of acute inflammation of the spinal cord with overwhelming diffuse hemorrhages into the gray matter, and to somewhat less extent into the white matter.

It seems important to draw an analogy between this case and two other cases of acute ascending paralysis, also recently under observation.

The evidence tends to show that there are three clinical as well as pathologic types of acute ascending paralysis. My conception of the differentiation of the three will follow later.

In order to have the material before us, I shall at once describe this case of acute hemorrhagic myelitis, and later briefly the other two cases.

Case 1.—E. W., a girl of 20, about to graduate from a private school, gave the following history: Her parents are living and well. There are two other children, one well and the other nervous. No family disease is known.

* Read before the Section on Nervous and Mental Diseases at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

* On account of lack of space this paper has been abbreviated for The Journal. It will appear in full in the Transactions of the Section and in the author's reprints.

The patient was a "blue baby," and the blueness persisted throughout her life. She had been rather delicate, of a nervous type and had had to favor herself more than a normal child. She had done well in school, however, and up to five days ago appeared to be in her normal health. Five days ago she first noticed a numbness, accompanied by some weakness, in her left foot. The following day a similar condition arose in the right foot, and later this numbness and paralysis gradually crept up her body, so that on the third day the numbness extended as far as the chest and began to attack the left arm.

She was brought home at this time, and was attended by two physicians, who were undecided whether she was suffering from hysteria or from some spinal cord lesion.

On the next day she had for several hours very severe pains, starting apparently in the spinal region and extending down both legs, especially the left. About this time also, her right arm became involved, the neck became somewhat stiff and she was practically completely paralyzed, except for her head, though certain weak movements of the right hand were possible.

At this time, that is, on the fifth day, I saw her in consultation with Dr. Kendall Emerson, and made the diagnosis of acute ascending paralysis. The temperature at this time was 103. The whole body was a grayish blue. The finger tips were markedly clubbed. There was practically complete anesthesia and muscular paralysis below the neck. The patient was unable to control the bladder and rectum. On the left leg was a large burn, 6 inches across, of which she was not aware, produced the night before by a hot water bottle. The pupils were equal and reacted normally to light. The neck was only slightly rigid. The tongue was dry and coated. The heart was rapid, 120, but not markedly enlarged and no murmurs were heard. The patient was conscious and perfectly clear mentally. The speech was unaffected. The respiratory muscles were just becoming affected, deep respiration absent. No glands were palpable.

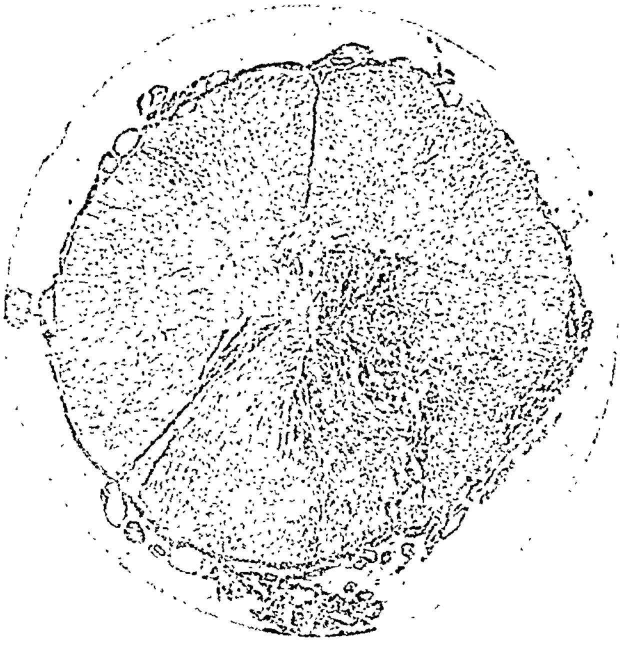

Fig. 1.—Case 1, E. W. Cord showing large area of hemorrhage in posterior horn.

I ordered immediate removal to Memorial Hospital, after first doing a lumbar puncture and withdrawing 15 c.c. of a somewhat turbid and markedly blood-stained fluid. The pressure of the fluid was somewhat above normal. The blood stain was evidently not due to trauma by the puncture, as all the fluid withdrawn was of the same nature. Subsequent examination of this fluid showed a marked excess of blood cells, an enormous excess of polynuclear white cells, some of them more or less disintegrated, and no bacteria. Cultures were taken from the fluid but no organisms could be grown. The globulin reaction was positive.

At the hospital the patient was made as comfortable as possible. She had no pain, but felt as if her body was heavy and she had an increasing sense of exhaustion. She was put on liquids and hexamethylenamin, 20 grains, every four hours.

Her entrance to the hospital was at 8 p. m., May 25, 1914. At that time her white blood count was 12,300; hemoglobin 80 per cent.

She did not sleep well that night on account of inability to move and a sense of weakness. Toward morning the respiration became more shallow and cyanosis increased. Suddenly at 9:45 a. m. respiration stopped practically without warning. A few moments later the heart beats ceased.

Permission was given for necropsy, which was performed by Dr. Kinnicutt at 1:30 p. m.

Anatomic Data.—Body of a well-developed young woman, markedly cyanosed.

Head: On section of the scalp there is a large amount of dark fluid blood. On removal of the skull-cap the longitudinal sinus is distended with dark fluid blood. The dura is not adherent, the meningeal vessels are injected, and the convolutions are somewhat flattened. On section of the brain: The ventricles contain no excess of fluid, but throughout the cerebral cortex are scattered numerous minute hemorrhagic areas.

Spinal Cord: The sections throughout its length show extensive areas of hemorrhage within the cord, especially into the gray matter, often entirely replacing the normal markings. There is no excess of spinal fluid and no evident induration around the meningeal covering.

Body: On section the subcutaneous fat is considerable in amount. The peritoneum is smooth and glistening. The appendix is normal. The lower border of the liver in the right mammary line is at the costal margin. The pleural cavities contain no free fluid. The lungs are salmon red in color and on section yield a large amount of pale, frothy fluid. The pericardium is normal. The heart is somewhat enlarged. On section the left ventricle wall is thickened. The papillary muscles are hypertrophied. The valves are normal. The foramen ovale is patent. The liver on section yields a large amount of dark fluid blood and shows "nutmeg" markings. The spleen is enlarged, firm, dark purple in color and on section yields a large amount of dark fluid blood. There is a small accessory spleen at its lower pole. The kidneys are enlarged. The capsules peel easily, leaving smooth surfaces. The abdominal organs otherwise are not remarkable.

Sections of the brain and spinal cord are placed in alcohol or 10 per cent. dilution of liquor formaldehydi for further examination. The bulk of the spinal cord is put into sterile glycerin for shipment to the Rockefeller Institute for Medical Research.

Microscopic Examination of the Brain and Cord: Paraffin Cresyl Violet Sections.—Cortex: Section 1: Precentral. The pia is of normal thickness. It contains small numbers of lymphocytes and numerous large endothelial cells, many of which are laden with blood pigment. Cortical lamination is normal and the nerve cells stain well. A mild satellite reaction is present in the deeper layers. Small amounts of green pigment are seen about some of the cortical capillaries, but otherwise the vessels are normal.

Cord: Section 1: About second segment (Fig. 1). Macroscopically, a large area of hemorrhage is seen, occupying the anterior and posterior horns of one side and extending anterolaterally to the periphery. Microscopically, there is found a disruption of the nerve tissue in the hemorrhagic area and a marked edema of that side of the cord. Smaller hemorrhages are scattered about the large focus. The reaction of the nerve cells varies. An occasional one is shrunken and angular, but the majority stain well, even those situated in the hemorrhagic area. There is no undue satellitosis. A heavy perivascular infiltrate of lymphocytes, together with a few polymorphonuclear leukocytes, is present. No plasma cells are seen. The vascular endothelium is not remarkable. Numerous glia cells with large vesicular nuclei and visible cytoplasm are present in both gray and white matter. In the central part of the hemorrhagic focus are large numbers of polymorphonuclear leukocytes and areas in which the tissue stains a dull, diffuse blue, suggesting necrosis. The opposite side of the cord shows a small area of hemorrhage, considerable edema of all the structures, and a mild lymphocytic perivascular exudate.

The pia is comparatively unaffected by the process, showing only occasional lymphocytes about the vessels.

Section 2: Lower cervical. Changes in the cord are similar to those in Section 1. There is a mild lymphocytic infiltration about the branch of the anterior spinal artery in the anterior fissure, and scattered lymphocytes among the anterior and posterior root bundles.

Section 3.—Lower dorsal. Very marked edema throughout the cord, which, with several large areas of hemorrhage, distorts the outline of the gray matter. Perivascular exudate as in Section 1. There are collections of lymphocytes, polymorphonuclears and large mononuclear cells in the pia about the points of exit of the anterior roots. There is no exudate, however, among the nerve bundles themselves.

Alzheimer's Lichtgrün Stain.—Cortex: Large granules staining with osmic acid are found rather abundantly in the cells in the perivascular spaces of the white matter, and to a small extent in the vascular endothelium of both cortex and white matter, and in a few nerve cells. No ameboid glia.

Lumbar Cord: Very heavy black deposits in the nerve sheaths everywhere in the white matter and in the nerve roots. Numerous glia cells with large vesicular nuclei and ameboid bodies are present in the white matter. These cells frequently contain vacuoles or black granules. The cord is infiltrated with hemorrhage.

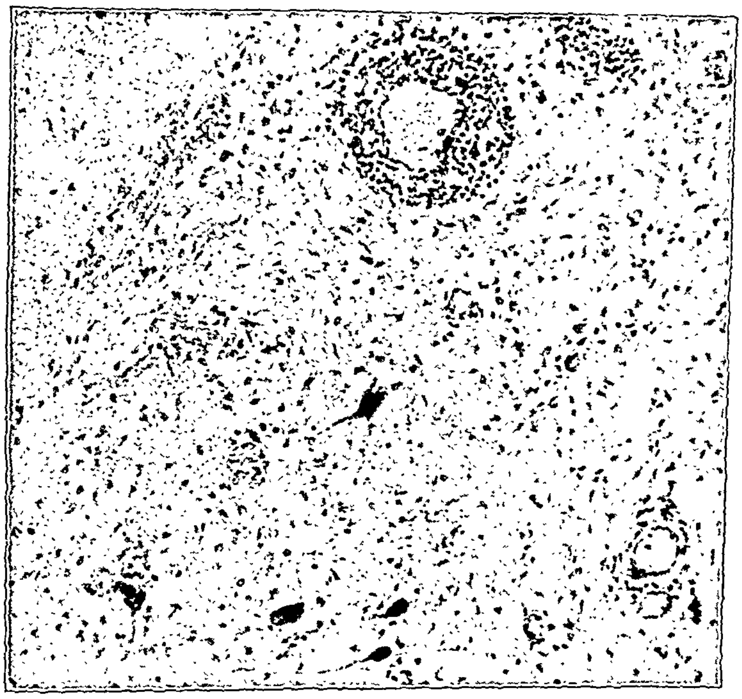

Fig. 2.—Case 1, E. W. Dorsal cord. An area from the anterior horn, showing lymphocytic perivascular infiltration. The nerve cells are intact.

Mallory's Phosphotungstic Acid Hematoxylin Stain. — No increase of fibrillar glia in cerebrum, cerebellum or cord. Examination of numerous cresyl-violet, thionin and Zenkereosin-methylene blue sections reveals no bacteria.

Summary.—An acute diffuse inflammation of the cord, characterized by extensive hemorrhage, heavy perivascular infiltration of lymphocytes, combined with smaller numbers of polymorphonuclear leukocytes, ameboid glia and fatty degeneration of the fibers in the cord and nerve roots. The nerve cells are in general well preserved, and there is no neurophagic activity. The centers of the large hemorrhagic foci show beginning necrosis with large numbers of polymorphonuclears.

The cortex shows a mild meningeal lymphocytic reaction, small deposits of lipoid in nerve cells and vascular endothelium, occasional perivascular lymphocytes and phagocytes, and in one section a marked satellite reaction with slight degenerative changes in the nerve cells.

As I intimated in the beginning, little success has been met in the search for cases like the one just reported. Of course a number of cases of anterior poliomyelitis have been reported with more or less hemorrhage into the gray matter, also many cases of more or less diffused myelitis, with hemorrhage. None of these, however, seem to correspond exactly to my case.

Wyss reported before the International Congress in 1898 a case of hemorrhagic myelitis and phlebothrombosis of the spinal cord, in a girl of 12 years. This process, however, was found to be dependent on a tumor of the cervical cord, and pathologic lesions did not extend above this area.

Warrington and Owen have since reported a case somewhat similar. The history is as follows:

> A man 41 years old. Illness began with chill, and three days later he had a temperature of 101. He then seemed to improve, but four days later he developed sensory and motor paralysis of both legs, with sphincter involvement. The paralysis ascended during the next four days until the respiratory center failed.
>
> At necropsy the cord at various levels showed masses of intraspinal hemorrhage, more severe in the dorsal region, and corresponding chiefly to the anterior spinal system of arteries. A distinctive feature was the great dilatation of the small vessels, in both gray and white matter. The pia also showed greatly distended vessels and cell extravasation. Under high power the vessels showed wall thickening and neighboring necrosis of tissue. The cornual cells and nerve fibers exhibited all degrees of degeneration when near the vascular disturbance. Beyond these zones the nerve structures were intact. The brain above the medulla was normal. No micro-organisms could be detected.

This case, though dissimilar, is more like Case 1 than any other I have found. By way of comparison, let us now consider Case 2.

Case 2.—E. C., a young man of 26, of previous good health, was occupied as a chemist in a rubber mill.

Three weeks before I saw him in consultation with Dr. Prouty of North Brookfield, he began to complain of headaches and feeling tired. No marked symptoms, however, developed until four days before, when the patient complained of slight numbness and weakness of both legs. This gradually became more marked, and three days later there was slight drooping of the left eyelid, with extension of the weakness to the thighs.

On physical examination, July 16, 1913, patient appeared fairly well nourished. Pupils reacted normally. There was slight impediment of speech and left facial paralysis. The knee jerks were absent, also the plantar and Achilles reflexes. Weakness of the legs was marked, but sensation was unimpaired except subjectively. Patient was sent to Memorial Hospital and lumbar puncture done at once.

Spinal fluid examination: Pressure normal, fluid clear, globulin positive, Fehling's reduced. Cell count 14, practically all lymphocytes.

The following day patient was unable to stand and paralysis was beginning to involve both arms. Two days later the muscles of the abdomen and chest as well became involved, causing more shallow respiration. The cranial nerves other than the seventh showed no definite involvement. The paralysis progressed, and the patient died of respiratory failure on July 26. The temperature had not reached 99 at any time and the pulse rate varied from 80 early in the illness to 120 toward the end. Urine was normal except for slightest traces of albumin.

Blood Examination: Hemoglobin, 90 per cent.; leukocytes, 11,100; erythrocytes, 5,628,000. Differential: Polymorphonuclears, 71 per cent.; lymphocytes, 21 per cent.; large mononuclears, 6 per cent.; mast cells, 1 per cent.; eosinophils, 1 per cent.

Necropsy.—By Dr. Hunt, three hours after patient's death. Nothing remarkable about the viscera of the chest and abdomen except that the distal part of the ileum was considerably injected and there appeared to be a general enlargement of the intestinal lymph nodes. Many of these nodes were the size of a cranberry bean and firm to pressure. The kidneys were slightly enlarged, but had normal markings and freely removable capsule.

The spleen was slightly enlarged and showed some signs of congestion. Cultures taken from the heart and subdural space failed to produce any organisms. On removal of the calvarium an excess of edema and considerable vascular congestion was noted in the meninges. The arachnoid was glistening and appeared somewhat less transparent than normal. The meninges of the cord likewise gave the appearance of congestion and edema.

On fresh section of the cord and brain no gross pathologic lesions were evident.

It was planned to inject emulsions of spinal cord from this case into monkeys to help establish the etiology, but, on account of the absence of the laboratory staff from two hospitals, it failed of accomplishment.

For lack of space, the microscopic findings are only summarized in this report.

Summary.—A widespread degenerative process in the nerve cells of the cerebrum, cerebellum, medulla and cord. The affected cells are frequently surrounded by others which appear normal, and no particular groups can be said to be peculiarly involved. There is a moderate satellite reaction, moderate perivascular lipoid deposits, and slight perivascular lymphocytosis in both pia and nerve tissue. The nerve roots, both cranial and spinal, show small lymphocytic deposits.

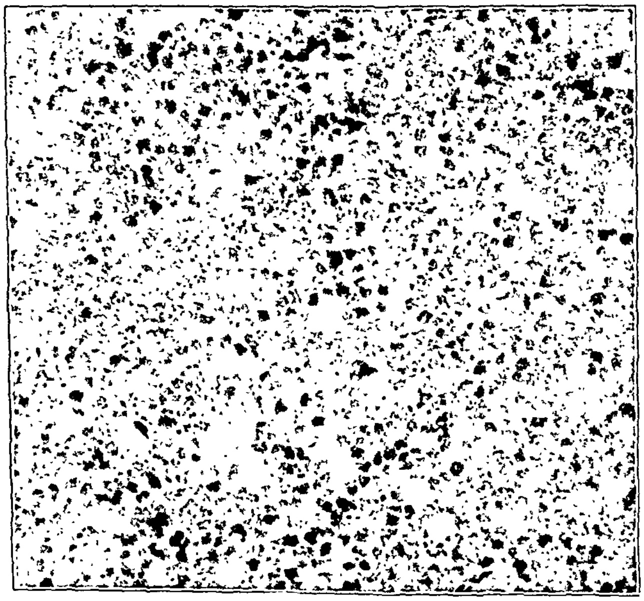

Fig. 3.—Case 1, E. W. Area of hemorrhage in the gray matter.

The pathologic picture is one which has been frequently described in cases of Landry's paralysis, that is, a widespread degeneration of the nerve cells with scanty perivascular exudate. The process in the present case is one which strikes the nerve cells differentially. Some fade out with, others without satellitosis. The picture is compatible with a purely toxic condition.

Further discussion of this case is postponed until after a brief summary of the following case.

Case 3.—A boy, 14 years old, was always well until Sept. 13, 1913, except for an accident to his head a year previous, at which time he received tetanus antitoxin. Two weeks previous to September 13, he had returned from a vacation at the shore in excellent health.

The early symptoms noted were headache and fever, which, on the afternoon of the 13th, reached 102.5. The headache, fever and malaise continued the next day, and during the night of the 14th paralysis of both legs developed. This paralysis gradually ascended during the next thirty hours until the thighs, abdomen and arms and respiratory muscles became in sequence involved. No pain was complained of. There was some paresthesia, but no actual anesthesia of the limbs. The deep reflexes of both legs and arms were absent. The paralysis was flaccid. Lumbar puncture was done by me at this time, September 16, on being called in by the family physician.

The spinal fluid was under moderate pressure, but was not turbid. The cell count was 68. Globulin was positive with both ammonium sulphate and Noguchi. Differential count (Alzheimer method): Lymphocytes, 0.83; endothelial cells, 0.12; polymorphonuclears, 0.5; plasma cells, 0.

Though the patient did not rally under treatment, he lived until 6 a. m., September 20, when both heart and respiration failed.

This case would be difficult to differentiate from the other two, without the aid of a spinal fluid examination, but with the differential cell count it must be put down as an anterior poliomyelitis (acute ascending type).

I regret that the family physician did not heed my request for a necropsy in this case.

The pathology of acute poliomyelitis being familiar to you, I am offering the following schematic differentiation of three types of acute ascending paralysis, as exemplified by the three cases above reported.

RELATION TO HEMATOMYELIA AND HEMORRHAGIC ENCEPHALITIS

While there is little chance of confusing as striking a case of hemorrhagic myelitis as Case 1 with a typical case of spontaneous hematomyelia, the clinical and pathologic relation of the two should be mentioned, especially as there have been many cases reported in which the clinical symptoms would leave one in doubt whether the process was inflammatory, hemorrhagic or both. Important clinical points to differentiate hematomyelia from acute diffuse hemorrhagic myelitis are: the absence of fever, the suddenness of the onset without premonitory symptoms, often with acute pain, the rapid sequence of paralysis localized in the part corresponding to the hemorrhage, localized anesthesia, lack of progressive extension to new areas, normal white count and normal or nearly normal, spinal fluid constituents.

The pathologic lesions of hematomyelia may be distinguished by their circumscription, the absence of inflammatory products, the picture of blood extravasation transversely, with subsequent ascending and descending degeneration of the tracts, in some cases tubular hemorrhages in the gray matter, and, when not traumatic, intact meninges.

In comparing hemorrhagic myelitis to hemorrhagic encephalitis, or encephalomyelitis, as a pathologic process, certain resemblances appear. For instance, both have the ear marks of an infectious etiology, the hemorrhage being evidently secondary to an inflammatory process in which the meningeal vessels are involved. Strümpell's first case of acute hemorrhagic encephalitis, it will be recalled, followed a bronchopneumonia. An enlarged spleen and other signs of infection were noted. Cultures from the brain, however, were negative. He assumed a primary local infective agent with secondary hemorrhages.

D'Allocco, too, reported a case of acute polioencephalitis in a child, with sudden onset of inflammation symptoms. At necropsy there were vascular occlusions of the cortical vessels following an endophlebitis or endarteritis.

Langbein and Oeller discuss at length the pathology of a case of acute hemorrhagic encephalitis occurring in a woman of 35 years whose acute symptoms lasted only two days. Death occurred one-half hour after lumbar puncture. The spinal fluid was under some pressure and was blood stained. It showed a positive globulin and microscopically a great excess of polymorphonuclear leukocytes but very few lymphocytes. All cultures remained sterile. On section the brain showed areas of thrombosis and hemorrhagic transudation. These authors regarded it as difficult to determine whether the thrombosis was primary or secondary. Because of the infiltration extending to all the vessel coats and even to the connective tissue, and the presence of meningeal affection, an inflammatory origin would seem likely; the absence of encephalitic changes, however, led the authors to theorize that the extensive arterial oozing may have been due to the thrombotic plugging of the veins. An interesting feature of this case is that the patient had a patent foramen ovale, though no mention was made of clinical phenomena therefrom. The spinal fluid characteristics, with excess of blood and polymorphonuclear cells, are in striking accord with my Case 1.

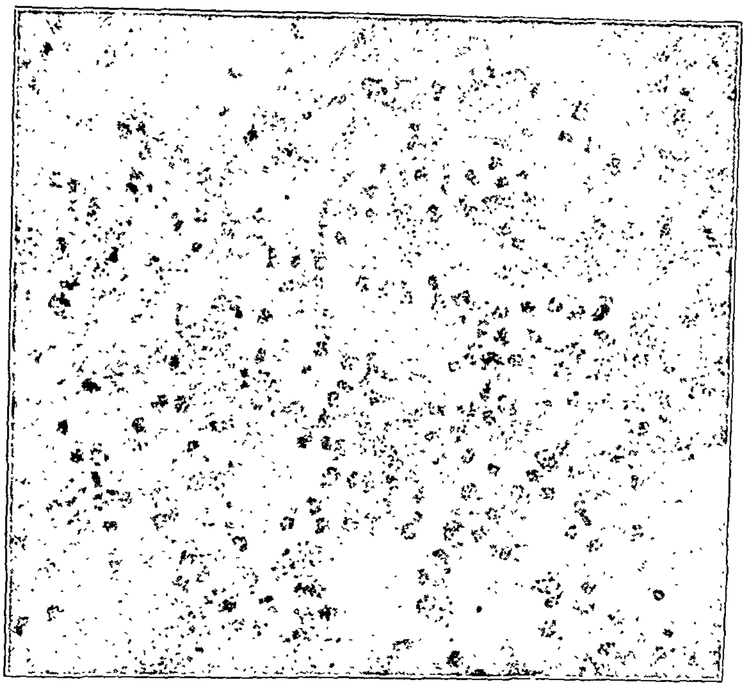

Fig. 4.—Case 1, E. W. Exudate, showing the large proportion of polymorphonuclear leukocytes, beginning necrosis and the presence of blood pigment.

ETIOLOGY

In the absence of positive proof of the presence of organisms in Case 1, all cultures being negative, and no bacteria found in tissues, we must resort to theoretical grounds for probable etiology.

Barlow, Schiff and several others have reported cases of myelitis consequent to measles, typhoid and other infectious diseases, and I now have under observation a case of localized myelitis following pneumonia. The primary symptoms in Case 1, however, were confined to the spinal cord.

Though this girl was generally fatigued, no evidence as to the point of entrance of an infective agent is at hand. That an infectious agent was at work, however, is suggested by the temperature, white count and prostration, which were in contrast with Case 2.

The pathologic findings, moreover, bear convincing evidence of an infectious as against a purely toxic reaction, as characterized in Case 2.

In spite of these appearances, it is safe to say that the ordinary infectious organisms are absent, as are, apparently, the ovoid bodies and toxic products of anterior poliomyelitis. At any rate, no characteristic reaction was produced in monkeys by injection of the glycerinated cord from Case 1.

The primary locus of the inflammation in myelitis has led to spirited discussion; whether in the circulatory apparatus as advocated by Mayer and Schmaus,

TABLE 1.—DIFFERENTIAL DIAGNOSIS

	Ascend. Hem. Myelitis	Landry's Paralysis	Poliomyelitis
Onset	Sudden constitutional symptoms. High fever. Severe pains in legs.	Mild prodromata. Paresthesias. Little or no fever. Pain absent.	Sudden constitutional symptoms. Fever early. Headaches, backaches.
Course	Short duration after hem. occurs. Continuous fever. Complete sensory and motor paralysis, ascending type. Peripheral nerves not involved. Cranial nerves not involved. Sphincters paralyzed. Respiratory failure.	Duration may be prolonged. Fever absent. Motor paralysis complete, only slight sensory. Asc. type. Peripheral nerves occasionally involved. Cranial nerves occasionally involved. Sphincters intact. Respiratory failure.	As paralysis appears, fever begins to subside. Motor paralysis of certain limbs. Mild sensory, or absent. Peripheral nerves seldom involved. Cranial nerves seldom involved. Sphincters occasionally involved. Resp. or heart fails.
Elec. React.	Course too short for abnormalities.	Normal faradic. Normal galvanic.	R. D. develops in paralyzed limbs.
Atrophy	None	None	*In paralyzed limbs.*
Recovery	Not in typical cases	Occasionally complete, even after nearly complete paralysis.	In most cases. Atrophy of paralyzed limbs with contractures.
White Count	High	Normal or slight	High early, slight later.
Spinal Fluid—			
Pressure	Plus	Normal	Plus.
Aspect	Bloody	Normal	Normal.
White Cells	100 +	Under 20	20—100.
Red Cells	Profuse	None	Occasional.
Lymphocytes	Moderate	Occasional	Profuse.
Endothelial Cells	Occasional	Rare	Occasional.
Polymorphonuclears	Profuse	Rare	Rare.
Plasma	Occasional	Rare	Occasional.
Disintegrated	Plus	None	Rare.
Globulin	2 plus	Plus or minus	Plus.

the ganglion cells (Charcot), or the glia tissue (Goldscheider, Marinesco). While the evidence in our case points to the primary involvement of the blood vessels, especially as the nerve elements are practically intact except where overwhelmed by the hemorrhage, it must be admitted that in those areas the destruction of all three tissues is fairly complete. Leyden observes that primary hemorrhages of the spinal cord are exceedingly rare, except those due to concussion, and concludes that, anatomically, a sharp separation between primary hemorrhage with subsequent myelitis from primary hemorrhagic myelitis is only possible in the rarest cases.

Circulatory factors affecting the occurrence or extent of hemorrhage must have some consideration. For instance, the permeability of the vessel coats must be dependent on the individual resistance of those coats to the disintegrating power of the toxic products. A factor that needs consideration is the liquefaction or noncoagulability of the toxic blood. Still another is forced on us by Case 1, namely, the open foramen ovale. We can little more than speculate as to the impaired resistance of the imperfectly oxygenated blood and the abnormal duties which fall on the capillaries thereby, but it cannot be disregarded as a factor, after its occurrence in this striking case and the case of Langbein and Oeller above referred to.

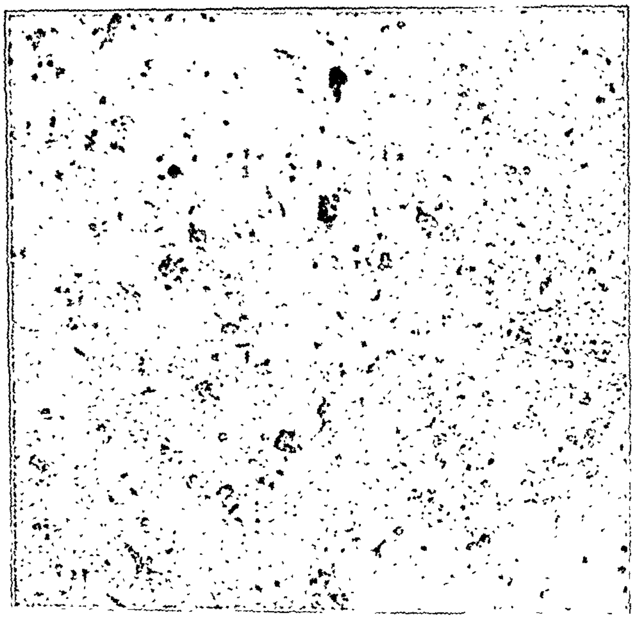

Fig. 5.—Case 2, E. C. Nucleus of VII, showing degeneration of the nerve cells and the presence of satellites.

Transmissibility.—It may seem unnecessary to discuss the transmissibility of hemorrhagic myelitis when the agent is unknown, but it may be helpful to draw a contrast on an etiologic basis between the three cases reported above. Assuming that Case 3 was a fulminating case of poliomyelitis, the success of Flexner, Noguchi and others in direct transmission of the disease to monkeys, would warrant the expectation of a similar result from this boy, had his spinal cord been obtainable. On the other hand, the glycerinated cord from Case 1 produced no lesion in monkeys, and, so far as this evidence goes, the condition is not similarly transmissible.

The foregoing data likewise are of some importance in making a differential diagnosis between the three types of ascending paralysis, since Case 1 has failed experimentally to produce symptoms of poliomyelitis in monkeys, while Case 2 is typical of ascending toxic paralysis (Landry) from no case of which, so far as I can ascertain, have the globoid bodies been developed or poliomyelitis caused in monkeys.

In this connection I might state that, in a recent personal communication, Dr. Flexner states that he is unaware that any positive infections of monkeys have occurred from cases of typical Landry's paralysis.

It may be remembered that Dr. Gordinier reported before the American Neurological Association last year a case of Landry's type; the spinal cord was then in the hands of Dr. Noguchi for inoculation. Evidently the inoculation in this case was unsuccessful, for a recent communication from Dr. Noguchi fails to throw any light on the transmissibility of this disease.

The procedure which to me appears to give the greatest aid in practical differentiation of the three types is the spinal fluid examination, especially the cell count by the Alzheimer method.

Of course, the mere appearance of a fluid which is sanguinolent, that is, uniformly mixed with blood and not coagulated, indicates the hemorrhagic type, but the presence of an enormous preponderance of polymorphonuclear leukocytes over lymphocytes is an effective differentiation from either the Landry's or the poliomyelitic type. The differential count is even more necessary as between Landry's and poliomyelitis,

TABLE 2.—PATHOLOGIC DIFFERENTIATION

	Ascend. Hem. Myelitis	Landry's Paralysis	Poliomyelitis
Spinal Cord—			
Cells	Not degenerated	Degenerated	Degenerated.
Reds	Profuse	None	Few.
Lymphocytes	Increased	Few	Many.
Leukocytes	Many	Absent	Few.
Ameboid glia	Present	Absent	Present.
Endothelial cells	Present	Absent	Present.
Vessels	Engorged and ruptured	Changes slight	Engorged at anterior horns.
White matter	Edematous, infiltrated with hemorrhage. Leukocytes, lymphocytes, etc.	No edema. No hemorrhage. Occasional lymphocytes	No edema. No hemorrhage. No lymphocytes.
Gray matter	Same as white, cells intact or disintegrated	Slight, injected with lymphocytes. Cells degenerated	Marked infiltration with lymphocytes. Cells degenerated.
Blood pigment	Marked	None	Slight.
Lipoid	Cortex	Cord and cortex	Rare.
Periph. Nerves	Normal	Normal, or occasional involvement	Secondary degen. (motor).
Pia—			
Vessels	Engorged. Edema	Slight engorgement No edema	Slight engorgement. Slight edema.
Infilt. reds	Many	None	Few.
With lymphocytes	Few	Few	Many.
Polymorphonuclears	Many	None	Rare.

for the gross appearance may be identical and the globulin test is apt to be present in both, but any marked pleocytosis, especially of lymphocytes, with traces of blood or endothelial cells is a strong indication against Landry's type and in favor of acute poliomyelitis.

The comment of Dr. Flexner, who, with his staff, was good enough to examine pathologic specimens from this case as well as to inoculate monkeys with the glycerinated cord, was as follows:

> "I have examined the specimens and find the lesions as described by your pathologist. They are not typical of poliomyelitis. The only feature in which they resemble poliomyelitis is the infiltration about the vessels in the pia and in the gray matter; but the infiltrations there are relatively slight for the degree of hemorrhage and the cells in some places are chiefly polymorphonuclear and not lymphocytic. On the other hand, the nerve cells do not show the usual necrosis with invasion of leukocytes — or neurophages.
>
> "The inoculations of monkeys with the glycerinated cord were unsuccessful. This does not necessarily mean that the specimen was not derived from a case of poliomyelitis, since it is not possible to transfer all specimens of glycerinated cord from cases of poliomyelitis to monkeys; but taken together with the nontypical character of the lesions I am inclined to think that the case was probably not one of epidemic poliomyelitis."

While it was not my intention to enter the arena of discussion regarding the nosology of acute inflammatory conditions occurring to the spinal cord, I find myself interpreting the suggestions which the foregoing cases seem to bring.

On general principles I believe that names should be descriptive of pathologic processes, and this precept has evolved the somewhat unfamiliar title of my paper. No other designation seems fitting to describe Case 1.

When we come to Case 2, its striking resemblance to the original case reported by Landry in 1859 makes us confident that it belongs to this group, so peculiarly free from macroscopic lesions.

The view held by some authors that no case showing the slightest microscopic change from the normal can properly be called Landry's seems to me untenable. In the first place, it ignores the fact that modern laboratory methods and equipment bring to light lesions which would have been undiscovered not so many years ago. Further, it is reasonable to suppose that any etiologic factor virulent enough to cause death must be productive of pathologic changes, whether or not they escape the microscope. These changes naturally become more marked, too, according to the nonresistance of the victim's tissues.

It seems that we should rely more on the type of tissue changes which accompany the clinical data and determine whether they appear to be toxic or grossly inflammatory.

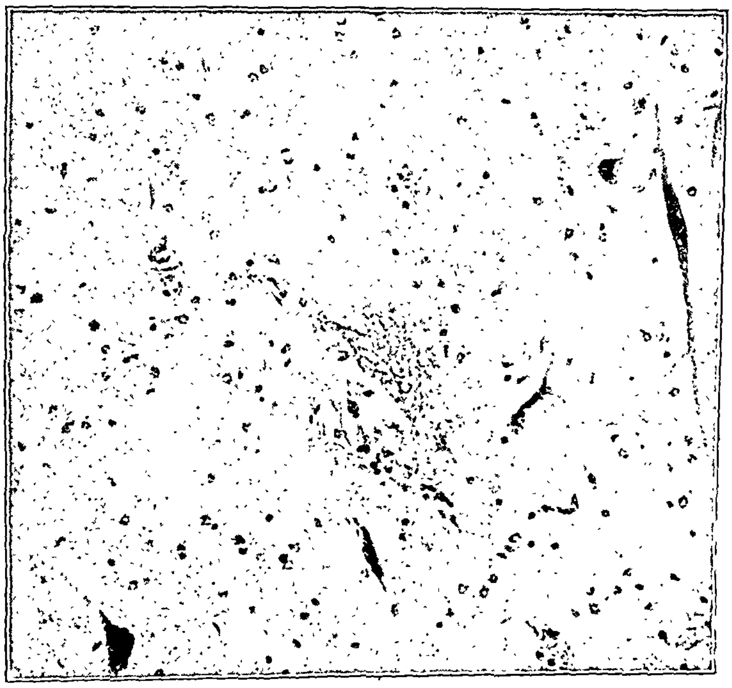

Fig. 6.—Case 2, E. C. Lumbar cord, showing cells of the anterior horn. Small numbers of lymphocytes and an area of fibrin network about a vessel. A degenerated cell on each side of the vessel.

In going over the literature I am not unmindful of the confusion which seems to exist in the minds of many as to the meaning of Landry's paralysis, and, in a measure, I sympathize with the accumulated opinion of Wickman, Taylor, Schmaus and others that the advisability of retaining the title is questionable. Unless, however, these or other authors supply the proof that Landry's paralysis and anterior poliomyelitis are identical it seems our duty to remember the type even though we forget the title.

The suggestion of Taylor to include practically all inflammatory conditions of cord and brain in the term "poliencephalomyelitis" appeals through its convenience, even as the all-inclusive term "psychoneurosis" in functional disorders, but if we all gather under one roof let us erect partitions in their proper places lest we sleep in the kitchen.

By continued animal experimentation and toxicologic research these myelitic diseases must yield up their true etiology and take their corners. Our pride in the work of Flexner, Noguchi and others should make us bent on furnishing them glycerinated material especially from Landry's type of paralysis, at the earliest opportunity, that our knowledge may increase. Until the time, however, that our laboratories can pin a label on the factors responsible for the three types above reported, I trust it has not been amiss to call attention to their apparent differentiation.

SUMMARY

An acute ascending hemorrhagic myelitis, as exemplified by Case 1, seems to occupy a unique place allied to, but not identical with, either myelitis or hematomyelia. Its clinical resemblance to acute ascending paralysis, either of the poliomyelitic or Landry's type, is striking, though closer analysis of symptoms and pathologic findings points to the existence, by the clinical data before us, of three distinct types of acute ascending paralysis.

Further confirmation of these types must wait on definite laboratory differentiation, which seems every day to be nearer completion.

25 High Street.

ABSTRACT OF DISCUSSION

Dr. Charles R. Ball, St. Paul: In my own work I have been somewhat uncertain as to the etiology of the cases grouped under the heading Landry's paralysis. Whether there is an ascending paralysis of an entirely different origin than the one caused by an acute poliomyelitis seems not as yet to have been proved. In spinal fluid examinations it is very important to differentiate between hemorrhages due to perforations of the blood vessels made at the time of the puncture and hemorrhage from some other cause. Centrifuging the fluid is perhaps the best means of making this differentiation. In recent hemorrhage, after centrifuging, the spinal fluid becomes perfectly clear; in old hemorrhages, however, it always shows a yellow tinge due to the presence of the hematin in it. It seems to me that being absolutely certain as to whether the hemorrhage was caused by an accident in puncture, or by the disease itself was one of the most important points to be established in determining the diagnosis in Dr. Burley's cases.

Dr. Benjamin T. Burley, Worcester, Mass.: I quite agree with Dr. Ball that it is very important to get spinal fluid without traumatic blood. It is usually fairly readily told whether the blood is traumatic or not, because usually the traumatic puncture shows blood at first and becomes clearer later. There is a typical appearance to blood which is thoroughly mixed with a spinal fluid and with increase of cells, for which some one seems to have coined the word sanguinolent. Unless one gets a satisfactory puncture the first time, it is advisable to repeat the puncture later.

KNEE JOINT DISABILITY CAUSED BY HYPERTROPHY OF THE ALAR LIGAMENTS *

ROLAND O. MEISENBACH, M.D.
BUFFALO

Notwithstanding the well-defined surface anatomy of the knee joint, especially in its anterior portion, it is not always a simple matter to differentiate the actual condition within the joint in some of the disabled knees which come to us for relief. This statement is confirmed by many writers, and it appears several times in the literature. This is true especially in those cases which do not give classical symptoms of one or the other of the many conditions which are constantly being encountered in joint surgery.

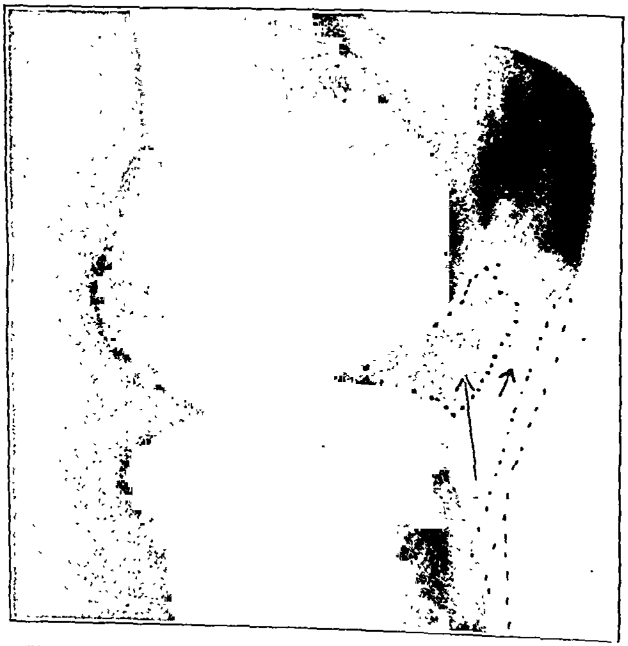

Fig. 1.—Patellar tendon, infrapatellar fat space and hypertrophied alar ligaments.

Not alone in the acute knee, but also in the chronic, do we frequently notice that definite subjective symptoms are absent. This, I believe, is one of the reasons for the frequency with which an acute disability of the knee joint is tolerated by the patient and terminates in a chronic disabled knee. Either the patient expects spontaneous relief, or the condition is deemed not direct enough for active interference.

The knee joint is constantly exposed to injury; this injury may be from external or from internal sources. The external sources comprise weak feet, irregular shoes, faulty alignment of limb following fracture of the leg or thigh, or both, besides the leverage twists, wrenches and actual direct violence.

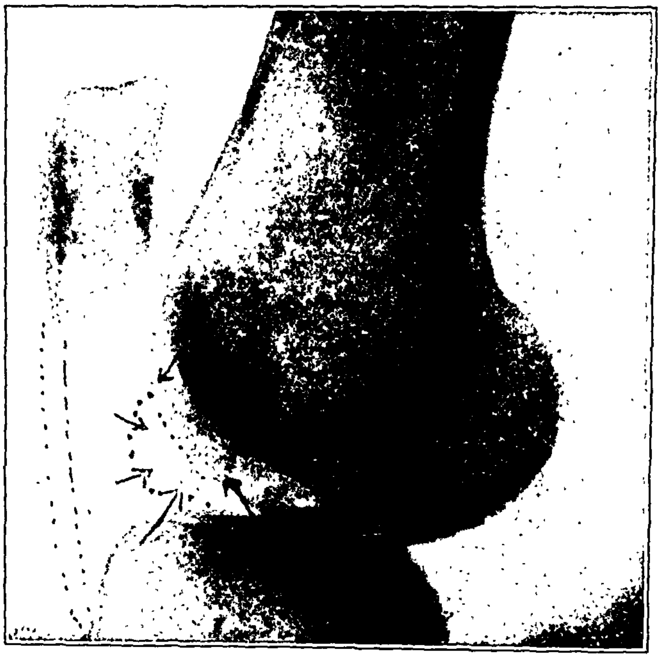

Fig. 2.—Dark mass, irregularly defined and mottled. Hypertrophied alar ligament. Note sesamoid bone in posterior part of joint.

The internal injuries may be induced by the knee joint's mechanism or a concomitant pathologic condition, or both.

THE KNEE JOINT

Considering the fact that the knee joint is one of the most important, largest and quickest joints to become injured, one would expect that its internal arrangement, as far as the anatomy and mechanism are concerned, would be well understood by all who have to do with this joint. Its mechanism is not stable, and its anatomy differs in many instances.

Perhaps the extreme range of motion which the knee joint exerts is the cause of the variation; at any rate, I believe that many of its soft parts, especially in the anterior portion and those which have to do with the lubrication, are constantly subjected to change.

The function of the synovial membrane and its different parts, namely, (*a*) ligamentum mucosum and (*b*) alar ligaments, is to lubricate the cartilaginous articular surfaces of the gliding parts.

The anatomy of the knee joint is described by Tenney in a most thorough manner. I wish here only to emphasize some facts and to describe that which pertains to this paper, namely, the alar ligaments.

ALAR LIGAMENTS OF THE KNEE JOINT

Normally, the alar ligaments are wing-shaped folds of synovial membrane extending from the mucosa, and are in my opinion part of the lubricating tissue.

---

* Read before the Section on Orthopedic Surgery at the Sixty-Sixth Annual Session of the American Medical Association, San Francisco, June, 1915.

be at times confusing, especially when the patient gives a history of kneeling, or the bursitis is mild. The knee itself is not swollen, and on the lateral aspect of the patella in the joint line nothing abnormal is felt. However, if the bursitis is due to systemic infection, then again we may have it associated with hypertrophy of the alar ligaments.

TREATMENT

There is only one permanent treatment for knee joints with hypertrophied alar ligaments; that is, their removal. Temporary relief, or symptomatic relief, may be given in some cases without removal. Limiting the motion of the knee and strapping give relief to symptoms only, and should not be advised except in rare instances, as enumerated above. The operation of arthrotomy, advised by many, if done in conservative and skilful hands, offers very little danger, and the old idea that an operation on the knee joint means a stiff knee is, I am glad to say, past. Formerly, perhaps, this belief was well founded; but with improved operative technic in these cases the danger is at a minimum, both as to obtaining a stiff knee and as regards sepsis; it is, in fact, no greater than in some of the other surgical procedures of the day.

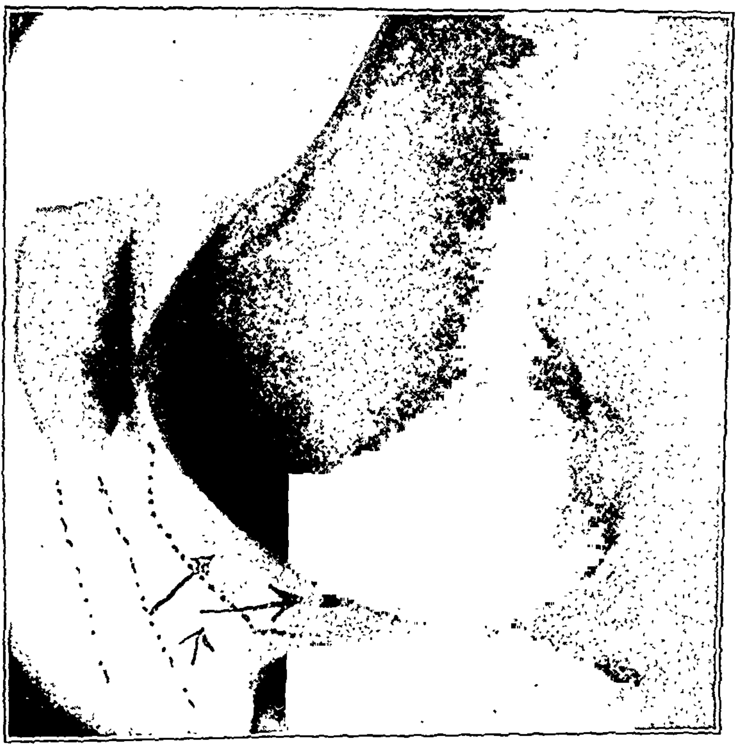

Fig. 7.—Note dark joint interspace.

In the technic of arthrotomy for the purpose of removing alar ligaments, certain principles must necessarily be observed, the same as with any other arthrotomies of the knee joint. First, there should be perfect asepsis; second, the incision should be as small as possible; third, the knee joint should be in a position of semiflexion. All bleeding should be checked before the capsule is opened; the capsule should not be held with hemostats. The finger need not enter the knee joint.

In removing the alar ligaments, they should be clamped at their base with a very fine hemostat, removed above the hemostat with scissors so as to insure no hemorrhage within the joint. Rarely tying within the joint is necessary. The capsule should be closed with silk or chromic gut and the knee joint bottled tightly and not drained. Passive motion should be done early, and the patient may walk as soon as the incision is firm. A few cases cited below will serve as an illustration:

Case 1.—Mr. B., gardener, aged 22, operated on Nov. 3, 1911, gave the following history: Two months previously, while lifting sod, using his right knee joint to assist the spade, he found his knee going weak. He gave up work and found that whenever he bent his knee or attempted to get out of a chair, he had pain. After resting the knee joint it grew better; but as soon as he attempted to walk much or ride a bicycle, the knee became painful. The knee was not swollen, and no crepitation was felt, but patient complained of pain after the knee was bent in extreme extension and flexion. A roentgenogram was taken.

A diagnosis of hypertrophy of the alar ligaments was made. The knee joint was opened by an incision on the inner border of the patella. The capsule was noted to be drawn into the joint, and when the capsule was opened, the knee joint was held in position of semiflexion. After retracting, it was noticed that two or three tabs extended from the mucous membrane in the anterior portion. The fibrous band could be seen tensely stretched, apparently from the ligamentum mucosum down to the surface of the tibia, suggesting that synovial tabs had become adherent. These tabs (alar ligaments) were removed, and the joint closed tightly. There was very little bleeding during the entire operation. Motion of the knee joint was begun on the seventh day and convalescence was uneventful. Patient returned to work.

Case 2.—Mr. G., aged 19, athlete, seen Dec. 21, 1911, gave a history of suddenly having his right knee become weakened, and at times painful. He said that he had had the habit while walking of throwing his knees in strong extension. The knee occasionally became swollen, but did not lock. A roentgenogram was taken.

The anterior portion of the joint showed a slightly dense shadow in the region of the ligamentum mucosum. Examination of the knee showed that the surface anatomy was apparently normal; no crepitation was felt on motion, and no swelling. The right foot was considerably pronated; otherwise the patient was in excellent health. Blood count negative.

A diagnosis of hypertrophied alar ligaments was made. Operation, Jan. 5, 1912. Incision on inner aspect of patella. Knee joint opened according to special technic; synovial membrane relaxed; no fluid in joint; alar ligaments removed; no other tabs protruding from synovial membrane. Patient had an uneventful recovery. Symptoms disappeared. Patient seen three years after the operation; no recurrence.

Case 3.—Mr. J., chauffeur, aged 21, had niesserian infection one year ago. Previously had been treated for flatfoot. To all appearances perfectly well, but while driving his car noticed that his right knee was painful and slightly swollen. This swelling has persisted for several months. Slight thickening felt on the internal and external aspect of the patella. Roentgenoscopy revealed thickening in anterior portion of the joint, extending well into the joint.

A diagnosis of hypertrophy of alar ligaments was made. July 18, operation, arthrotomy of right knee joint. Incision of internal aspect of patella. On opening the capsule considerable fluid emitted from the joint. Synovial membrane injected and quite vascular. Ligamentum mucosum and alar ligaments thick and boggy. Alar ligaments removed, considerable hemorrhage, one squirter from each tied. Knee joint closed tightly, no drainage. Convalescence uneventful. Patient able to continue occupation as chauffeur up to the present writing.

Case 4.—Miss P., aged 33, occupation institutional work Has always been well, with the exception of her knees, which have been painful intermittently. Patient has been accustomed to kneel frequently, many times coming down firmly. Last several months has noticed when she attempts to get up there is sharp pain, which disappears after a while, but recurs. Examination of knee joint shows slight roughening of the skin over the patellar bursa of both knees. Knee joint not swollen and no crepitation. Extreme flexion elicits some pain. Roentgenogram taken and a rather diffused shadow of homogeneous consistency seen a short distance below patella.

Diagnosis after eliminating other conditions, hypertrophy of the alar ligaments. Operation, arthrotomy, May 14, 1915. After capsule incised, ligamentum mucosum and alar ligaments were seen to be congested and one internal alar ligament adherent to the femur. The alar ligaments were removed; knee joint closed. Recovery uneventful.

CONCLUSIONS

In presenting this paper, it was my object especially to call attention to the variety of conditions which may be found in disabled knees, all of which may present more or less some of the same symptoms, but if carefully studied, will be found to be distinct entities; but more than that, to attempt to call attention to the type of knee joint which is so frequently seen, in which the symptoms are so irregular that only by a thorough search, and in some cases by means of eliminating the other conditions, the patient will obtain relief.

140 Allen Street.

ABSTRACT OF DISCUSSION

Dr. Fred. J. Fassett, Seattle: Dr. Meisenbach asked me to participate in this discussion, and I promised to look up my anatomy on alar ligaments and where they are to be found. In doing so I was quite impressed with the exact spot, because they lie just where I have found symptoms of a very definite nature that I have heretofore been unable to call by any name. I have been content with the general sweeping diagnosis of an internal derangement of the knee joint. The definite symptoms I speak of are these: Not the grating that accompanies damage to the bones, but a creepy feeling and soft crack which occur when you move the patella, as if it were rubbing over some pulpy substance. I should like to ask Dr. Meisenbach, in closing the discussion, to say a word about his method of approach to this region.

Dr. J. T. Rugh, Philadelphia: It has been my privilege to operate in about a dozen of these cases. To me the symptomatology is rather clearly defined, and it constitutes in my experience a distinct condition which in the vast majority of cases requires surgical interference for its correction. These cases, as I find them, usually present an intermittent hydrops; that is, there will be an injury to the joint from overuse of the part or from a blow or a fall, and this will be followed by an effusion into the joint, which subsides after a few days. After the subsidence of this joint swelling, examination of each side of the ligamentum patella will give a sensation as of a substance rolling away from the thumb. One can feel the mass slipping under the thumb. My plan has always been to make a lateral incision, either internal or external or both, according to the conditions present, and through that incision remove this ligament. It is very easily done with a pair of scissors. The result has been functionally perfect.

Dr. Roland Meisenbach, Buffalo: In answer to Dr. Fassett's question, I might say that the lateral incision has the advantage that in most knee joints by this route the alar ligaments are immediately exposed and are easily reached without exposing very much of the knee joint itself. It also has the advantage that in many of the knee joints there is very little hemorrhage by this incision. It is essential to take further precaution to prevent hemorrhage within the joint, also to prevent hemorrhage before opening the capsule. I would like to emphasize the fact that the capsule should not be clamped with hemostats, but should be held apart with silk retractors. I have always felt that the alar ligaments have been very much neglected, and I was glad to hear Dr. Rugh confirm this belief. I think that in many of our knee joints we obtain a history of intermittent symptoms, but these intermittent symptoms do not necessarily extend over regular times, as in intermittent hydrops. In my earlier cases I believed that the hypertrophy of the alar ligaments explained intermittent hydrops, but later experience has taught me differently. I wish also to emphasize the fact that patients suffering with hypertrophy of the alar ligaments assume a peculiar gait with a view of protecting their joint on all occasions. I believe this is partly psychologic, and partly due to the fact that the pain comes on suddenly and they expect it, but are unable to know exactly what motion of the knee joint brings it on. In some of the cases one should be conservative enough also to have the different laboratory tests made, and one should be on the lookout for other conditions, in which the hypertrophy of the alar ligaments may be a residual hypertrophy due to a general diathesis.

ROENTGENOGRAPHIC BONE CHANGES IN A CASE OF POLIOMYELITIS

G. B. HASSIN, M.D.
Attending Neurologist, Cook County Hospital

CHRISTINE LUKAS, M.D.

AND

R. O. BROWN, M.D.

CHICAGO

That the bones undergo atrophic changes in the course of poliomyelitis is a well-known fact, and the following case illustrates the extent such a bone atrophy may attain:

History.—Man, aged 39, entered the Cook County Hospital with a complete paralysis of the lower limbs. The patient states that he has been unable to use his legs since the age of 2 years, when he sustained a fall, following which he was confined to bed for about two years. Until the age of 10 he lived at home, then for five years at an orphan asylum, and then was an inmate at the Dunning asylum up to the age of 34, whence he was transferred to the Oak Forest infirmary. Here, he states, the inmates began to accuse him of various things. He could hear them "talking" about him, "sneering" at him, and thinks it quite possible that "they have formed a conspiracy against" him. Any other diseases, including venereal diseases, he denies.

His mother died at Dunning insane asylum when the patient was about 5 years old. The cause was some form of insanity. The father died from an unknown cause when the patient was 12 years old.

Examination.—The patient is a rather poorly nourished middle-aged man, somewhat apathetic, but oriented as to time, place and persons. He answers questions intelligently, but is emotional when, with tears in his eyes, he complains of "charges" preferred against him and of the hospital not being "a safe place" for him. He cannot walk, and keeps the lower limbs flexed in the hip and knee joints, while the feet are drooping (Fig. 1). The legs cannot be extended beyond 135 degrees. There is some movement in the toes, which are irregular in their shape and growth. The second toe of the right foot is of the same length as the great toe, and the fourth is of the same size as the fifth. The left fourth toe is much smaller than the fifth. The size of the lower limbs is greatly diminished, entirely out of proportion to that of the upper half of the body, resembling the extremities of a boy. Thus, the length of the lower limbs is 21 inches, measured from the popliteal fold to the postero-inferior border of the os calcaneum, as against 31 inches, which is about the average normal length for his age. The length of the feet, measured from the postero-inferior border of the os calcaneum to the extremity of the third toe, is 7 inches for the right, and 6¾ inches for the left (normal about 9½ inches). The circumference of the lower limbs, at the level of 10 cm. above the external malleolus, is 5¼ inches on either side (instead of 8 inches); 12 cm. below the knee joint it is 6¼ inches on either side (the normal average is about 11¼ inches). At the level of 15 cm. above the knee it is 9¾ inches, against 15 inches, which is the average normal. All the muscles of the lower limbs appear greatly reduced in volume, especially the extensors of the legs and feet, where fibrillary twitchings are marked. The movements, as abduction, adduction of the legs, flexion and extension, are possible, but greatly limited, and the muscle power in the atrophied limbs is almost entirely absent.

The electric examination reveals a complete reaction of degeneration in the muscles and nerves of the legs.

The tendon reflexes, as knee jerk and achilles, are absent on both sides, the plantar, cremasteric and abdominal present. The pupillary reflex and eye grounds are normal. Sensory disturbances, as well as those of the bladder and rectum, are absent.

Of other anomalies we should point out the small size of the head (microcephalous), and a marked lumbar lordosis and, at the level of about the second sacral vertebra, a dimple in the skin with a lipomatous nodule below it.

Thus, the examination shows a great decrease in size, or atrophy, of the lower limbs, which are diminished both in length and in width. The cause of this atrophy is undoubtedly an old poliomyelitis, in the form of a flaccid paraplegia, combined with a paralytic lordosis, secondary contractures in the knee joints and some signs of degeneration, as evidenced by the disfiguration of the toes, and small-sized head. The mental condition of the patient speaks for dementia praecox.

The paralysis and the atrophies are perfectly symmetrical in character, the shortened lower limbs resembling, when compared with the rest of the body, those of a 10 or 12 year old boy. The undersized condition of the lower limbs is to be ascribed to the atrophy of the muscles and bones. The muscular atrophy can be determined by means of the electric current, or palpation, and direct measurements, while that of the bones can be determined by means of roentgenoscopy. This shows (Fig. 2) that the femur and both bones of the leg are greatly reduced in size. The bones are thin, appear smooth, polished as it were, and deprived of their usual characteristics. The bone seems to be somewhat transparent, the thickness of the solid bone substance being greatly reduced. These changes are confined to the diaphysis only, and do not involve the epiphysis. All these changes, so well to be seen on the roentgenogram, were pointed out long ago by Joffroy and Achard[1] before the discovery of the Roentgen rays. They explained the changes by the lack of muscular activity, which is mainly responsible for the shape and irregularities of the bones. These, of course, must disappear or undergo some transformations in old cases of poliomyelitis, like ours, in which muscular contractions are absent.

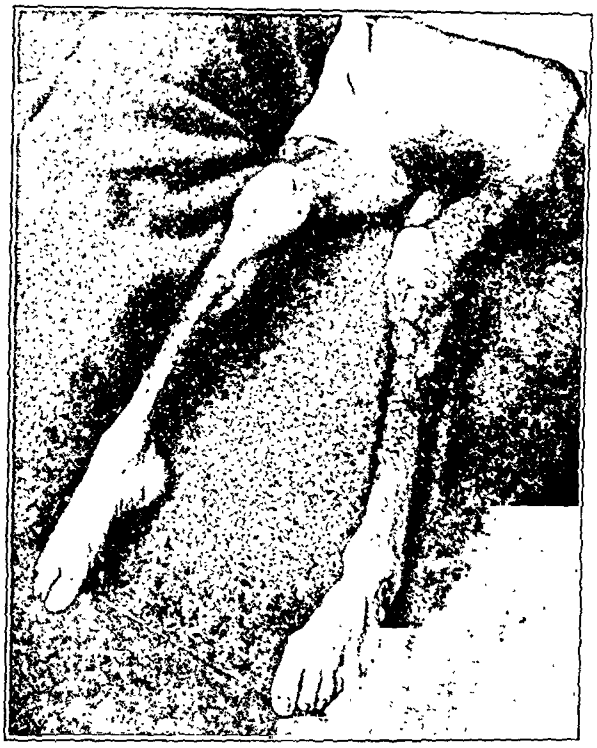

Fig. 1.—Lower limbs of patient.

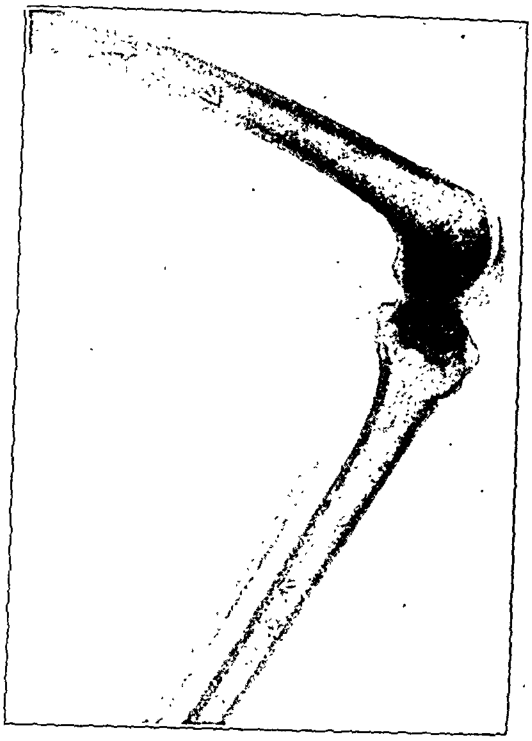

Fig. 2.—Roentgenogram showing reduced size of bones.

These findings were afterward fully confirmed by Archard and Levy[2] through roentgenoscopy, and also by Oppenheim[3] and Bruns.[4]

Mental Defectives.—We have come to realize that our moral judgments are inextricably mixed up with social judgments; that general intelligence, learning, experience, etc., are brought into play in the exercise of every moral judgment; that millions of brain processes are involved in every thought and act, and conduct is an expression of the whole machinery at work; that there is no ground for the presupposition of a separate sense that sits in judgment, approving or disapproving of our actions. In short, a mentality incapable of forming moral judgments is likewise incapable of forming normal judgments along other lines, and is (*ipso facto*) a defective mentality, and is demonstrable by a thorough examination of general intelligence, judgment, reasoning capacity, etc. These are mental defectives, and not moral imbeciles.—V. V. Anderson, *Boston Med. and Surg. Jour.*, Sept. 23, 1915.

Therapeutics

PNEUMONIA

As the season approaches when pneumonia begins to be more frequent, until, in February or March, it generally reaches its highest death rate, it is well to reconsider some of the fundamentals in its treatment.

In many cities and in most states pneumonia has become the chief cause of death, tuberculosis having given way to this infection. The pneumococcus is ever ready to attack any debilitated individual, and especially to add its attack to that of the influenza bacillus. The very fact that the death rate from pneumonia is increasing shows that the prognosis is not good. If the disease tends to recovery like most acute infections, it certainly needs a great deal of aid. A fatal issue can readily be hastened, if not precipitated, by misdirected efforts and by neglect. The great seriousness of this disease is due to its effect on the heart; consequently the care of the heart is of paramount importance.

The treatment may be discussed under various heads, as follows:

1. *Rest.*—This must be as near perfect as possible. Not only should the room be situated for the best possible fresh air, but it also should be as quiet as possible. Friends and relatives should not disturb the patient. The more he talks and the more he thinks, the more rapidly will his heart pulsate, the more rapidly will he breathe, and the more mentally restless and consequently sleepless will he be. Sleep and a quiet heart are more essential in pneumonia than in almost any other disease. Perfect rest does not mean that the patient should not be turned frequently, or that he should not have at times several pillows; in fact, it has lately been advocated for a patient with pneumonia to sit up once or twice a day for a short time, even in a chair. This is perhaps a little too radical, but the point should be emphasized that the circulation in the lungs should be changed by alterations in position. A patient with pneumonia should not lie flat all the time. Hypostatic congestions readily occur with pneumonia, especially if the heart's action is impaired.

2. *Fresh Air.*—It has now long been demonstrated that a pneumonia patient has less fever, a slower pulse, a better blood-pressure, and breathes less frequently in cool, clean air than in close house air, and this whatever the season. Wards on the roof are very valuable for hospitals in the treatment of pneumonia as well as tuberculosis. The balcony, veranda, or even tent treatment of pneumonia is advisable at certain seasons of the year with certain types of patients, when such facilities are obtainable. It is always essential that the room of a pneumonia patient should have more than one window — the more the better — and that these windows should be widely open, except when the patient is being bathed or his clothing is being changed. Under any circumstances it is not necessary to have a draft of cool or damp air blowing directly over the patient's face, but screens can modify the direction of the wind or brisk air. Very young children and old people should not be subjected to severe cold atmosphere, while older children and strong adults may not only endure cold, but may even thrive in it. The fresh air or outside air treatment of pneumonia is subject to the modification of common sense. If a patient's body and extremities become cold or chilled when properly covered, the fresh air treatment is too severe.

3. *Diet.*—The food of the patient should represent something of all the elements required for nutrition. This means protein in the form of eggs, meat juices, properly made meat broths, and milk. The eggs may be in any form desired, except fried. The milk should never be sufficient in amount to cause intestinal gas, or gastric indigestion.

The next very necessary element for nutrition is starch, and it should not be forgotten that many a seriously ill patient finally dies really of acidemia from carbohydrate starvation. Egg albumin and milk do not represent the proper food for patients who are ill more than a few days. The starches can be presented in cereal gruels, rice, oatmeal, malted milk, toast, crackers, and even by potato soup. Ice cream, custard, chocolate, and a small amount of cane sugar or milk sugar are all of value.

The patient should be allowed plenty of water, as, however valuable a deprivation of water may be in aborting an acute cold or acute bronchitis, it is not advisable to withhold water in pneumonia. Unless there are edemas from a failing heart or from kidney insufficiency, plenty of water will increase the amount of urine and therefore remove more products of waste metabolism from the blood, thus tending to prevent the toxemia from the disease which is to be feared. It promotes the secretion of the skin, which is desirable, and also renders the exudate in the lungs less tenacious and more easy of expectoration.

Elements of nutrition which must not be forgotten are: sodium chlorid, iron when meat juices are not given, and lime when little milk is given, and especially if there is much blood in the expectoration. The sodium chlorid can be given by properly salting the patient's food, especially his gruels, and even at times his milk. The iron may be given as a saccharated oxid of iron (*Eisenzucker*) 3-grain tablet, crushed at the time of taking, or crushed by the patient's teeth, and administered twice a day. The lime may be given as lime water in tablespoonful doses in milk or in water, three or four times in twenty-four hours; or it may be given in a capsule as calcium glycerophosphate, in 0.30 gm. doses.

The whole question of the diet is also subject to common-sense modification to fit the patient. There are enough suggestions in the foregoing to furnish sufficient nutrition while meeting almost any patient's desires. The main object is (1) to avoid starving the patient on any element that he requires to promote his metabolism and keep up his nutrition; and (2) to avoid gastric and intestinal indigestion. If the tongue is heavily coated and the patient is so seriously ill that he does not digest properly, 5 drops of dilute hydrochloric acid in water, directly after his protein meals, will aid the stomach digestion and often clean the tongue. It may also stimulate intestinal digestion. If there is much intestinal gas the diet should be closely studied by the physician to ascertain which food is causing it. Provided that the blood-pressure is not too high, that the heart is not too irritable, and that the patient is not too nervous and restless, coffee morning and noon, or coffee in the morning and tea at noon, or tea both times if the patient prefers, is advisable and often beneficial. Tea and coffee should be considered as representing caffein, and if the action of caffein is desirable, these beverages may be given. They should not be given in the late afternoon or evening, as they tend to prevent much needed sleep.

OBESITY AND STARVATION

The essence of the successful method for reducing weight in those suffering from obesity lies in keeping the intake of energy below that of the output. Theoretically, complete fasting constitutes the most prompt method of accomplishing the end sought. It is a well-recognized fact, however, that starvation prolonged over a period of more than a few days, either voluntarily or as an incident of disease, may lead to unpleasant symptoms. Headache, nausea and dizziness portend the existence of conditions that are not exactly normal, and frequently they can be made to disappear promptly by the ingestion of even a little food. Most modern "treatments" for obesity, therefore, consist in underfeeding rather than complete fasting, particular care being directed to conserving the protein of the body so that the reduction in weight shall represent essentially a loss of body fat oxidized to furnish energy to the underfed individual.

In the course of observations on the voluntary fasting of two exceptionally obese patients of the Massachusetts General Hospital in Boston, Folin and Denis[1] noted the usual development of the indications of "acidosis," that is, an increased elimination of acetone, aceto-acetic acid, and particularly of beta-oxybutyric acid and ammonia in the urine. In one of the subjects the figures were exceptionally high, amounting to over 18 grams of beta-oxybutyric acid and no less than 2.5 grams of ammonia-nitrogen during the fourth day of starvation. The appearance of such products in these amounts is in accord with the widespread scientific belief that the "acetone bodies" are derived chiefly from incompletely oxidized fat. When the obese are compelled to depend on their store of fat for maintenance, one might reasonably expect these intermediary products to "crop out."

In order to relieve the subjective symptoms associated with this fasting acidosis, Folin and Denis interrupted the period of complete starvation by a period of very moderate diet just sufficient to cause the disappearance of the "acetone bodies" from the urine. Thereupon a second fast was begun. Here the striking observation was made that the acidosis did not manifest itself anew until the third day of this fast, and the patient felt well until the fourth day. After an interspersed repetition of "low" diet a third fast was begun five days later. Here again the onset of acidosis was even slower than during the second period. These facts, supported by confirmatory evidence in a similar case, have suggested to the observers that with regard to the complete oxidation of body fat in starvation, the human organism is capable of at least a certain amount of adaptation, and that it is this individual factor rather than the tendency to obesity or the extent of the fat deposits in the body which chiefly determine the onset and the degree of acidosis. Folin and Denis conclude that one of the effects of repeated fastings is habituation to the complete oxidation of mobilized body fat, and a consequent retardation of the development of acidosis.

These results suggest, in the words of their discoverers, that one perfectly safe, rapid and effective method of reducing the weight of very obese persons is by a series of repeated fasts of increasing duration, the ammonia or beta-oxybutyric acid determination being used as a guide to the length of each fast.

THE RHYTHM OF THE HEART

During recent years there has been such extraordinary progress in our knowledge of the rhythm of the heart and its disturbances in disease and under the influence of drugs that probably many physicians have rather hazy ideas as to the present status of knowledge on these subjects. Progress in this field has resulted from the development of methods which have enabled clinicians to apply to the human heart some of the knowledge already available in regard to the heart of the lower animals. On the other hand, the clinical application of these methods has revealed many hitherto unsuspected conditions and raised new questions in physiology, pathology and anatomy; this has greatly stimulated further investigation along these lines. The result has been greater progress within the last few years than in as many decades previously. In this work anatomists, physiologists, pathologists, pharmacologists and clinicians have all had a part. Nor has the work been confined to one country: the Dutch (notably Einthoven), the English (Mackenzie, Keith, Lewis and Cushny for example), the Germans and Austrians (His, Hering, Wenckebach, Rothberger and Winterberg and others), Americans (Erlanger, Cohn, Eyster and Meek, to mention only a few) as well as representatives of many other nationalities have made important contributions.

The two methods which have contributed most to the solution of problems concerning the disturbances of rhythm in the human heart have been the use of venous tracings and of the electrocardiograph.[1] Both of these methods show whether or not each beat of the ventricle is preceded by one of the auricle; they show accurately the interval of time elapsing between the auricular and the ventricular contractions; in cases of abnormal or disturbed rhythms they throw much light on the point of origin of such rhythms.

---

[1] Folin, Otto, and Denis, Willey: On Starvation and Obesity, with Special Reference to Obesity, Jour. Biol. Chem., 1915, xxi, 183.

Among the numerous points established by these investigations (combined with and controlled by experiments on the hearts of the lower animals) the following may be mentioned: Normally each heart beat begins in a small area of the right auricle beginning between the opening of the superior vena cava and the auricular appendix and extending toward the inferior vena cava; that is, in, or in the region of the specialized tissue known as the sinus or sino-auricular node. From this point the wave of excitation passes over the auricles causing the auricular contractions; it passes through the auriculoventricular bundle of specialized tissue (the bundle of His) to the ventricles, which contract at a definite and measurable interval after the auricular contraction. This constitutes the normal or sinus rhythm of the heart. If, however, for some reason this sinus region ceases to inaugurate impulses, or if the impulses are comparatively weak, or if they fail to reach other parts of the heart, then one or more of the latter may assume this function of "pace maker." One of the most important of the regions which may inaugurate a rhythm for the heart is the auriculoventricular node, which lies in the interauricular septum at the beginning of the auriculoventricular bundle. Impulses arising in this region reach the auricles and ventricles simultaneously or almost simultaneously, and the chambers of the heart contract at the same time; in other words, an auriculoventricular rhythm replaces the normal sinus rhythm. Or the impulse may arise still lower in the auriculoventricular bundle; thus, apparently, it may arise now in the branch passing to the right, now in that passing to the left ventricle. Many other forms of irregular rhythm, which it is impossible to consider here, have been described.

Other disturbances of rhythm result when some or all of the auricular beats fail to reach the ventricle; in other words, when there is a partial or complete "heart block." Heart block, as is now quite generally known, may result from an anatomic interruption of the connection between the auricles and ventricles, as is often the case in the Adams-Stokes syndrome; or the interruption may be only functional. In either case the ventricles develop a rhythm of their own more or less independent of that of the auricles. Functional heart block may result from increased activity of the vagi. It has long been known from experiments with animals that one effect of stimulation of the vagi is a lowering of the ability of the tissue connecting auricles and ventricles to conduct impulses from the former to the latter. Similar results may be obtained in man by pressure on one vagus, or the vagus may be thrown into increased activity reflexly, by pressure on the eyeball for example.[2] Digitalis increases the activity of the vagus center; one of the consequences is impaired conduction of impulses from auricle to ventricle and the well known condition of heart block so often occurring in the use of this drug. In auricular fibrillation, a condition which occurs in very many cases of valvular heart disease and in which the normal auricular beat is replaced by a condition of fibrillation in which many hundreds of impulses per minute endeavor to reach the ventricle, digitalis, by increasing the resistance of the auriculoventricular bundle, and so reducing the number of impulses reaching the ventricles, protects and slows the latter. This is the generally accepted view of the action of digitalis in this condition, although some details of this explanation have been questioned. Or digitalis may, apparently, cause a condition of block in lower portions of the auriculoventricular bundle leading to marked changes in the character of the beat of one or other of the ventricles.[3]

Perhaps the foregoing comments will suffice to show that, although this recent work may at first thought appear to add to the complexity of an already complex subject, it in reality tends to simplify the entire subject by bringing various phenomena under a common viewpoint. It represents the stage of synthesis which always follows a more thorough study of natural phenomena.

DIETOTHERAPY IN DIABETES

It must be frankly admitted that the underlying nature of diabetes is still veiled in deep mystery. The number of individual important facts now known in regard to the disease is large. The earliest knowledge of the attending glucosuria has been supplemented by information about the condition of the blood — the hyperglycemia of diabetes — and by such investigations as have demonstrated beyond question that the capacity of the organism to destroy sugar is impaired.[4] Other details of the perversions of metabolism, such as the acidosis and ketonuria, have been brought to light. Drug therapy has largely been abandoned, and dietotherapy substituted for it. One who has followed the progress in the study of diabetes can understand the occasions for the successive changes in the proposed dietetic measures, which include all gradations of regimen from starvation or strictly carbohydrate-free dietaries, on the one hand, to the oatmeal or potato "treatments" at the other extreme. As an expert in this field recently remarked, physicians may well come to the conclusion, after reading some of the latest literature in this field, that all of our earlier views have been turned topsyturvy.

[3] Cases apparently of this character were reported, and the literature reviewed, by H. A. Christian (Arch. Int. Med., Sept. 15, 1915, p. 341).

[4] The Changing Theories of Diabetes, editorial, The Journal A. M. A., Aug. 2, 1913, p. 348; Two Theories of Diabetes, March 28, 1914, p. 1023.

An intelligent appreciation of the situation calls for a brief historical survey. The earliest attempts of the more modern procedure in the dietary management of diabetes aimed at overcoming the excretion of sugar, or reducing it to a minimum by restricting the intake of carbohydrate and, if need be, likewise that of protein, which was recognized as an added source of sugar in severe cases. This method of treatment met its difficulties in the appearance of ketonuria, with the attendant dangers of acidosis, leading to the dreaded coma. Nothing short of the administration of some carbohydrate seemed to avert this incidental feature of the severer types of the disease. It was at this period that certain special dietary schemes were attempted, such as the milk, rice and potato diets, respectively. Levulose was recommended as a carbohydrate toward which the diabetic shows special tolerance. None of these proposed devices for furnishing carbohydrate in some way more acceptable to the diabetic organism gained more than passing consideration. As a rule, they offered no advantage in treatment.

Through chance observations, von Noorden hit on the routine oatmeal treatment. In certain cases in which the patients were put on an exclusive diet of oatmeal, owing to digestive disturbances which they were subject to, von Noorden noticed that instead of an expected increase in sugar output, this actually decreased. Repeated similar favorable increases of tolerance led to the publication of the facts. The new mode of dietetic management, in which the administration of large quantities of oatmeal and butter for a few days is made to follow a few days of "strict" diet or so-called "vegetable" diet familiar to all dietotherapeutists, promptly called forth protest. Prominent investigators like Naunyn and Pavy denied the possibility of cure by feeding starchy cereals. Naunyn and his pupils attempted to explain the utilization data of the oatmeal administrations by the contention that the cereal carbohydrate becomes peculiarly prone to fermentative decomposition in the alimentary tract. It is destroyed without significant utilization, we were assured.

Despite its theoretical incompatibility and the outspoken criticism of well-known writers, the oatmeal treatment for certain types of diabetics has not been abandoned. From time to time, groups of successful cases have been reported by competent, unbiased clinicians. Every one who has achieved any success with the procedure has emphasized that a suitable preliminary strict regimen is indispensable to success, and also that the scheme fails in many instances. The striking character of some of the statistics, which show greatly improved tolerance after a few days of the oatmeal diet, as well as the character of the names attached to the reports, leaves the impression that some element of merit is hidden in the observations. The attempts at explanation have not been fortunate. At first it was believed that some specific chemical constituent of oatmeal other than starch is responsible for the increased carbohydrate tolerance and the amelioration of the ketonuria. This now seems unlikely. It was believed that oatmeal components might either act on the ductless gland mechanism in some undiscovered way, or render the kidneys less permeable to sugar. The more recent analyses of the blood-sugar content have withdrawn any probability of the latter explanation. Additional explanations need not be advanced here.

The supposed specificity of oatmeal in its favorable effect on the diabetic was gradually dispelled by the demonstrations, not very convincing at first, but more emphatic as the technic became more consistent, that other cereal products could be substituted with success. Blum, Petersen, Lampé, Klemperer and others have reported the occasional favorable use of a variety of natural products other than those derived from the oat seed. The list is not inconsiderable. In every case, however, emphasis appears to have been put on the necessity of restricting the carbohydrate intake to a single plant source, whether it be oat, wheat, buckwheat or a legume.

Falta[5] of Vienna now assures us that "mixed" carbohydrate treatment may equal the older procedures in its favorable influence on glucosuria and ketonuria. This extends the palatability of the diet in those cases in which this form of diabetic regimen is to be tried. As a rule it seems to be best to use the cereals in the form of gruels or porridges — not in a baked product — the reason presumably being connected with the different alimentary behavior of the two types of food product. Like the advocates of the oatmeal treatment, Falta insists that meat and protein from animal sources should be excluded, and plant protein substituted. The explanation for this is not clear. The contention is made that meat in largest degree interferes with the glucogenesis of the diabetic organism.

It should be borne in mind that these "cereal treatments" are not in the nature of permanent diets, but are merely interspersed in the midst of a fairly strict routine of carbohydrate-free living. This fact has not always been understood by practitioners. Highly advocated tentative dietary methods, whether they involve starvation and alcohol or mixed cereals, deserve intelligent consideration and trial under appropriate conditions. They must not, however, be allowed to overshadow the success of the current methods of diabetic dietotherapy, particularly in cases of only moderate severity; nor should they be permitted to furnish an argument for the unscrupulous vender of diabetic foods which are rich in starch, even though the label may be "within the law."

GOOD HEALTH COMMERCIALLY CONSIDERED

The final report of the Commission on Industrial Relations, created by act of Congress in 1912, has just been issued. While the findings and recommendations of this commission on labor conditions, industrial unrest, workmen's compensation, hours of labor, trade unions and other subjects connected with industrial conditions are of interest, the most important section of the report, from the standpoint of the physician and the sanitarian, is Section 16 on Industrial Conditions and the Public Health. Condensed into six pages are a number of startling statements for the first time given the authority and endorsement of a government commission. Under the direction of an officer of the Public Health Service, investigations were conducted by the commission which revealed the fact that while much attention has been given of late to accident prevention, yet accidents caused only one seventh as much destitution as does sickness. Each of the thirty-odd million wage earners in the United States loses an average of nine days a year through sickness, at an average cost of two dollars a day. The wage loss from this source is over five hundred million, while the added cost of medical care of at least $180,000,000 increases the total sick bill of the wage earners of the United States to $680,000,000 a year. From 30 to 40 per cent. of cases requiring charitable relief are due to sickness, while sickness among wage earners is primarily the result of poverty, causing insufficient diet, bad housing, inadequate clothing and unfavorable surroundings in the home. According to the commission, the surroundings and place of work and the personal habits of the worker are important but secondary factors. This means that while there should be no diminution in our efforts to secure better conditions in the factory, the office and the workship, the real solution of the public health problem lies in the improvement of the home.

Quite as important is the classification made by the commission of disease-causing conditions into three general groups: those for which the employer and the character of the occupation are responsible; those for which the public is responsible, and those for which the individual worker and his family are responsible. It has become a truism in public health work that fixing the responsibility definitely and beyond question is half of the battle for better conditions. The commission regards the employer as responsible for occupational diseases, low wages, excessive hours, work methods causing nervous strain and general insanitary conditions. The public is responsible for housing, water supply, food, drugs and community sanitation. The greatest share of responsibility, however, rests on the individual and, under present conditions, in the opinion of the commission, he is unable to meet this responsibility. The majority of wage earners do not receive sufficient wages to provide for proper living conditions. The present methods of disease prevention and cure are expensive, and sickness is most prevalent among those who are least able to purchase health. The commission does not anticipate any such rapid increase in the wages of all classes of workers as would permit proper living conditions and adequate medical attention, and therefore concludes that new methods of dealing with existing conditions must be adopted, based on the cooperative action of those responsible for these conditions. A system of sickness insurance is proposed as the most feasible single remedy. The right of the federal government to tax industries in a sickness insurance system has been recognized since 1798, when the law taxing registered vessels for the support of the Marine Hospital Service was passed.

An extensive scheme for a federal system of sickness insurance is outlined by the commission providing for a national sickness insurance commission composed of representatives of employers and employees in equal ratio, with the federal commissioner of labor statistics and the surgeon-general of the Public Health Service as ex officio members. It is interesting and encouraging to note, among the most important recommendations of the commission in this direction, that "correlation of the insurance system with the medical profession, the lack of which has been a serious defect in German and British systems, is absolutely necessary." Any one who has followed the development of industrial insurance abroad will admit that the opposition or at least the half-hearted cooperation of the medical profession, owing to the inequitable system of compensation and to the fact that no consideration was given to the medical profession in framing the various insurance schemes, has been a most important factor in the partial failure of these insurance systems. A trained medical profession is absolutely essential for the successful operation of any industrial insurance plan. The terms on which physicians are asked to assist in the operation of such a system should be fair and such as will enable them to do justice to their responsibilities. This has not been true either in England or in Germany. More than this the physician does not ask. Less than this he should not be expected to accept. The recommendations of the commission on sickness insurance and on the improvement of health conditions among wage earners are worthy of the most careful consideration both by employers and by labor unions.

THE OCCURRENCE OF CREATININ IN PLANT PRODUCTS

Physiologists ordinarily associate creatin and creatinin with animal products. Among animal tissues and organs, there is a marked inequality in the distribution of these specific compounds. They preponderate in the muscles to an extent which makes the other sources seem quite inconsiderable. For example, recent analyses by Janney and Blatherwick[1] give comparative figures in one species as follows, in terms of milligrams per hundred grams of organ: muscle, 470; brain, 114; testes, 181; pancreas, 18; liver, 20; kidney, 14; spleen, 30. Even among animal species, the occurrence of creatin in muscle is not an invariable feature, for it is entirely wanting in the contractile tissues of invertebrates, such as the shellfish which we eat.

For some time the creatinin output in the urine has been looked on as an index, in some degree, of the endogenous metabolism of vertebrates, and of man in particular. In order to estimate this factor, it is, of course, essential that the diet shall be free from creatin and creatinin, which may reappear in the kidney output as products of exogenous origin. Accordingly, it has been customary to secure the appropriate dietary for estimations of endogenous creatinin output by excluding meat and other animal tissues from the ration. Vegetarianism has been assumed to furnish the appropriate diet here required.

Though much has been written on the relations of creatin and its derivatives or precursors to animal tissues and processes in biochemistry, the possibility of its occurrence outside of the animal kingdom has not been considered to any great extent until recently. Shorey[2] found creatinin in extracts of soils. The interpretation of this discovery was not easy, owing to the fact that the formation of creatinin in bacterial cultures in peptone mediums had previously been reported. It might, therefore, owe its origin to the agency of soil bacteria acting on nutrient products in the earth used. Sullivan[3] has called attention to the fact that most commercial nutrient "peptone" is of animal origin and may contain antecedent products which readily yield creatinin. He has, however, demonstrated that a trace of soil added to protein-free synthetic culture mediums may still give evidence of the formation of creatinin by micro-organisms.

The possibility that plants may furnish the creatinin found in soils was realized by Sullivan,[4] who found it in the vegetable kingdom for the first time in 1911. He detected it in wheat seeds and seedlings, in rye, clover and alfalfa seeds, in mature cowpea plants and in potato tubers. From the fact that creatinin was present in larger proportions in recently cropped soils, it was assumed that the presence of creatinin there is associated in some way with plant growth.

Quantitative data have recently been furnished by Sullivan.[5] Only a few parts of creatinin per million were found in the ungerminated seed of wheat and soy bean; but during germination the quantity may increase up to 65 parts per million. Japanese investigators have reported the presence of creatinin likewise in the seeds of the Adzuki bean, the kidney bean, the horse bean and green peas, and have identified the product by dependable isolation methods.[6] As has happened before in physiology, these facts serve to indicate that the relationships between animals and plants in respect to fundamental biochemical processes are closer than it was customary to believe before the advent of modern chemical investigations. From the standpoint of their bearing on diet problems, the quantities of creatinin in plants are probably far too small to command much attention. A growing knowledge of how it arises and what becomes of it in the plant economy may nevertheless help in the future to throw light on the still vexed questions of creatin-creatinin metabolism in man.
